"It is found that the only certain mode of retaining the pure flavour of the coffee, is to roast, pound, and boil it, all in quick succession, the roasted berries soon losing their flavour if laid by for a day, and the pounded coffee becoming insipid, even in a few hours. The Arabs of the desert, who are from necessity economical in the use of this article, follow the same process, even if they require only two cups of the liquid, roasting a handful of berries on an iron plate, pouding them in a pesle and mortar while warm, and the instant the water boils, which it generally does by this time the other preparations are completed, so that no time is lost, putting the pounded powder into it, and suffering it to boil, stirring it at the same time for about a minute or two, when it is poured out to drink. As the beverage is
COFFEE TREE.

This native North American tree is found as high northward as Upper Canada beyond Montreal, and on the southern shores of Lakes Erie and Ontario. It is, however, much less abundant in these elims than in the states of Kentucky and Tennessee, and in the tract watered by the Ohio and Illinois rivers, between the 35th and 40th degrees of latitude.

By the French of Canada this tree is called Chicot; by those of the Illinois Gros Fierier, whilst the inhabitants of the Western States call it Coffee Tree.

The presence of this tree, is an evidence of the richest lands, on which it habitually grows in company with the black walnut, red elm, poplar, blue ash, honey locust, and hackberry. These trees it equals in height, but not in bulk; for a coffee tree fifty or sixty feet high does not generally exceed twelve or fifteen inches in diameter. "In summer," says Michaux, "this tree when fully grown has a fine appearance; its straight trunk is often destitute of branches for thirty feet, and supports a summit not very widely spread, but of a regular shape and tufted foliage; such at least is its form in primitive forests, where it is confined by the trees which grow around it. In the winter when its leaves are fallen, the farness of its branches and the size of the terminal ones, which are very large in comparison with those of other trees, give it a peculiar appearance, somewhat resembling a dead tree, which it retains in the spring long after other trees are clothed in foliage. This is probably the reason of its being called Chicot, stump tree, by the French Canadians. To this peculiar character is added another of the epidermis, which is extremely rough, and which detaches itself in small, hard, transverse strips, rolled backward at the ends, and projecting sufficiently to render the tree distinguishable at first sight. I have also remarked that the live bark is very bitter, so that a morsel no bigger than a grain of maize chewed for some time produces a violent irritation of the throat."

The foliage of the coffee tree bears some resemblance to that of the black walnut. The flowers are white, and the fruit consists of large bean-like crooked pods, of a reddish brown colour, and of a pulpy consistency within. They contain several large, grey seeds, which are extremely hard. The French in Upper Louisiana call them Gourgane.

"The name of the coffee tree was given by the early emigrants to Kentucky and Tennessee, who wished to find it in its seeds a substitute for coffee; but the small number of persons who made the experiment abandoned it, as soon as it became easy to obtain from the seaports the coffee of the West Indies."

"The wood of the coffee tree is very compact and of a rosy hue. The fineness and closeness of its grain fit for cabinet-making, and its strength renders it proper for building. Like the locust, it has the valuable property of rapidly converting its sap into perfect wood, so that a trunk six inches in diameter has only six lines of sap, and may be employed almost entire. These qualities recommend it for propagation of the woods of the north and of the centre of Europe."

"The coffee tree was sent to France more than fifty years since. It thrives in the environs of Paris, where there are trees that exceed forty feet in height; but it does not yield fruit, and is multiplied only by shoots obtained by digging trenches round the old trees. The divided roots produce shoots three or four feet long, the first year. The young trees are sought, on account of their beautiful foliage, for the embellishment of parks and picturesque gardens."

A communication from Mr. M. D. Hardin, of Franklin county, Kentucky, published in the American Farmer (vol. 2), makes us acquainted with some interesting facts relative to the sensible properties of the fruit of the coffee tree, and its effects when eaten.

The subjoined preparation of the nut of the native coffee bean tree, or pea locust tree, "has," says Mr. Hardin, "been found to destroy flies more certainly than any preparation I ever saw. It is now used by many in this neighbourhood. I never heard of it until this season. There is no danger to children or any animal from the preparation. I have been familiar with the nut for more than thirty years; it grew in my father's yard, and is in abundance in my wood pastures. I have several times eaten the kernel of the nut raw, but never of many at a time—when roasted many are fond of them, and I have eaten a good many that way, I have never myself seen them used for coffee, but have heard of their being so used as a matter of curiosity not of choice or economy. The cattle eat the pods including the nuts in the winter, as they do the wild honey locust pods; but the nut owing to its hard shell does not digest, but passes off whole. I have known children eat the green glutinous matter within the pod, as they would that of the wild honey locust, but it brings on sickness and puking. The nut itself is so well understood to be harmless and edible, that the coffee-mill has been most usually made use of to prepare the nut for the flies."

"For destroying flies.—Take the nuts of the native pea locust or coffee-nut tree, crack them and take out the kernel raw; reduce them to meal or powder (a coffee-mill or mortar are commonly used), put this into as much sweet milk as would make it into a paste. To this add some sugar to make the flies more readily eat it, put it into a plate or other vessel, and set it where you want to destroy the flies."

The value by tale depends upon the age, reign, section of country, and other qualifying circumstances, so that it cannot be precisely expressed in so small a compass.

By the Mint Laws passed by Congress in 1837, the eagle is to weigh 258.5 grains, the half and quarter in proportion; the dollar 412.5 grains, the parts in proportion. The relative value, therefore, of silver to gold, is 16:9984 to 1, or nearly 16 of silver for 1 of gold. In making this comparison, both the silver and gold are to be of the fineness of nine-tenths.

The coinage of silver in the United States, from 1826 to 1833, was nineteen and a half millions; that from 1834 to 1841 was twenty millions.

COLCHICUM (Colchicum autumnale). Common meadow saffron. A bulb throwing up a reddish purple flower without leaves in September and October: grows three or four inches high: found in moist rich meadows, but not common. It may be propagated from offsets in July. Every part of the plant contains an alkaline principle named Colchicum, which is a most violent purgative as well as narcotic. This active matter is extracted by wine, spirits of wine, and vinegar. A tincture of the bulb or of the seeds of colchicum, in the dose of twenty to thirty drops twice a day, has been found very useful in gout and rheumatism. It has been too commonly taken without medical advice, and much mischief has resulted. In an overdose colchicum is a virulent poison (Smith's Edw. Flora, vol. ii. p. 202).

COLD (Sax. col; Dan. kaal). See GASTRITIS, and Diseases of CATTLE, HORSES, &c.

COLE, or COLESEED (Celt. cool; Welsh, caul; Lat. Brassica napus). A variety of the cabbage genus, much cultivated in the east of England; it is sown from the middle of July to the end of August, either for autumn sheepfeed, or for seed (which is very rich in oil) for the following summer. The ashes of the burnt straw of coleseed are excellent dressing for clover. (Brit. Hist. vol. ii. p. 312.) See COLZA and RAPE.

COLEWORT. See CABBAGE.

COLIN, THE VIRGINIAN PARTRIDGE (Ortyx Virginiana). This bird has been introduced into England from the United States, and is a species of partridge. It lives on the borders of woods, among brushwood, or on the thick grassy plains. (Yarrell's Brit. Birds, vol. ii. p. 448.)

COLLAR (Span. collar; Lat. collarare). That part of the harness of a horse or other animal that goes round his neck and rests on the shoulders. For horses, they are mostly made of canvas, &c. stuffed with hair, tow, or straw, and covered with leather.

COLLEY, or COLLY. A kind of dog much prized by the Scottish drovers. See DOG, SHEEPHERD.

COLLEY SHEEP. A name for sheep that have black faces and legs. The wool of these sheep is generally very harsh, having hairs mixed with it.

COLLING, ROBERT and CHARLES. Two celebrated farmers of the county of Durham, who, by their skill, enterprise, and public spirit, not only secured for themselves the plaudits of after generations of farmers, but did honour to their country by the improvement which they effected in the Durham breed of short-horns, perhaps the most celebrated of all our modern breeds of cattle. It is not in my power to give any details with regard to their private history; their public efforts is all in which my readers will feel interested. The following account of the sale of their stock, and the enormous amount which it produced, will afford a much better view of their success as breeders than any eulogium of mine.

Charles Colling, of Ketton, near Darlington, made a very ample fortune. The price he obtained for his stock could hardly indeed have failed to have produced such a result: thus at his sale of improved short-horns, Oct. 11, 1810, the following were some of the prices obtain ed:

Robert Colling's stock was sold at Barrowton, near Darlington, September 29, 1818, when it produced for—

347
Charles Colling, after his retirement from business, resided at Croft, in the North Riding of Yorkshire, where he died January 16, 1836, aged 85. Robert Colling died in his 70th year, at Barmpton, near Darlington, March 7, 1820.

**COLT (Sax. colt).** A term applied to young horses. See Horses.

**COLT-EVIL.** In farriery, a distemper to which young horses are subject, consisting of a swelling in the sheath.

**COLTS-FOOT, COMMON.** *(Tussilago farfara).* Pl. 10, t. This is an herb of peculiar growth, very common in England on chalky or marly soil, in most situations. It is mostly found in fields that are over-cropped or exhausted, and often severely exercises the patience of the farmer. It may be eradicated by ploughing up the soil, carrying the plant away when rooted out, and laying the fields down to grass. The flowers rise in spring on stalks six or eight inches high, round, large, and yellow, like the dandelion; their stalks being thick, fleshy, scaly, and red coloured. Each stalk supports one flower. When the flowers have decayed, then the leaves appear on erect furrowed footstalks, broad and cordate, lobed and toothed, resembling the form of a horse's foot, whence the name. They are green above, and white and downy underneath. The leaves are used medicinally, and they dry well. A decoction of the leaves and roots, or a syrup of the juice, is useful in coughs, whence the generic name. The ancients inhaled the smoke for the relief of coughs.

There are two species of the colts-foot, butterbur, or Tussilago genus in the United States. See Nottall's *Genera.* The plant known in Pennsylvania and some other Middle States by the name of colts-foot is not of the same genus, but an *Asarum.* See Ginger, Wild.

**COLZA.** Though comparatively but little cultivated in England, and hardly known in the United States, colza is an article of immense importance in French and Flemish husbandry. It belongs to the cabbage family, and is cultivated for its oily seed, which are crushed and pressed for their oil, similar to flax-seed. The oil is used to burn in lamps, and for a great variety of useful purposes. The cake left after pressing the seeds, like that of rape, is an article regularly in the markets of England, France, Germany, &c., being purchased by farmers, who use it, either alone or mixed with other substances, as food for cattle, or to make into manure for various crops. In France, Germany, and the Netherlands, the cake is very often thrown into their urine-cisterns, where it soon becomes a very valuable ma-
When this is skilfully performed, the plantation may be effected with great regularity. In soils of moderate fertility, the plants need not be more than 9 inches apart in every direction. When the ground is very rich, they may stand about 12 inches apart; and when planted with the plough, every other row is left vacant, and the plants placed 9 or 10 inches apart.

In moderately fertile soils, the product of the colza is generally equal to, and sometimes a little greater than that of wheat. Thus, in soils which produce 20 bushels of wheat to the acre, 20 or 25 bushels of colza are obtained, and the product of rape has been nearly equal. But in more fertile soils the colza, when it has been well managed, far surpasses the product of wheat on the same soil, it being not unusual to obtain 28 or 30 bushels to the acre, on ground that will not yield more than 18 or 20 bushels of wheat. Sometimes, by very careful cultivation, and on ground of a very deep soil, especially when this is newly broken up, as much as 40 bushels of colza can be got from an acre, a larger product than could be expected from rape.

The chaff of colza and rape form very good food for woolly animals during winter. When given to horned cattle, it should be in the form of slop, made by mixing it in boiling water. Sheep eat the straw or stems very freely, when well kept and not too coarse.

When planted in rows, a hoeing or harrowing, by means of the cultivator, is generally given in the month of March. About the beginning of July, and sometimes even at the end of June, the navette, or rape, and winter colza arrive at maturity, the rape almost always 8 or 10 days the earliest. As the seeds of these plants shatter off very easily, it is necessary that, in harvesting, they should be cut before they become completely ripe. The most proper time is when the seed-pods begin to turn yellow and become transparent, and when the seeds are of a dark-brown, though still tender.

Though the grains of all the pods may yet be green, the greatest number will ripen in the stack or mow. Sometimes, when the crop has become very ripe, to prevent the loss of the seed, it should only be cut in the evening or morning, whilst it is covered with dew, or during a bright moonlight night. Twenty-four hours after reaping, or sometimes immediately after, if the planter is fortunate, the colza is put into cocks, the sheaves being carried to an elevated part of the field, and placed in cocks, the height of which must be double that of the stock of colza. In laying them down, the first sheaves are placed on the outside, and the next towards the centre. The cock gradually diminishes in diameter, till raised to the height of five or six feet. When the cock is two or three feet high, the stalks or stems have an inclination on the outside towards. This increases successively to the top, which is thus made to form a perfect cone. To keep out the rain, the top may be tied with a band of straw, willow twig, or branch of any other pliant wood. The cocks remain in this state until all the grains are matured. This generally requires from 8 to 12 days. If carefully put up, the cocks will be sufficiently protected against bad weather, except in case of powerful and continued rains, which would occasion still more damage to the crop in any other situation. The colza may also be put into large stacks, like those of wheat and other grain, very soon after it has been cut, and remain in this situation for a period. This is in the safest way of keeping the colza. But this method is more expensive than that of cocking, as it requires to be waggoned to the stack. The fermentation which always takes place in the cocks is very favourable to the grain, giving it a fine colour, and contributing qualities which are very desirable. The grain will only be injured, if it is heaped up whilst it is yet green or wet.

When the crop is small, it may be taken at once into a barn and thrashed off. In its transportation the seed is very apt to be shaken off, and the grain is carried to the wagons in cloths, and the wagon itself should be lined with some coarse and cheap stuff.

Large crops of colza or rape are generally thrashed in the field by the feet of horses, the place being covered with strong hempen cloth, stretched upon a spot from which all stones, &c., are carefully removed. If the colza has been put up in cocks, we carry the whole cock in a linen cloth eight feet square, which four men suspend to two long poles of light wood, eleven feet in length, attached to the two sides of the linen. After spreading the cloth along the side of the cock, the two other poles, of the same length as those described, are passed under the cloth, which is thus raised up altogether and placed upon the cloth, to be carried to the thrashing-floor. When this is sufficiently filled with colza, spread evenly about two feet in thickness, and first beaten down by the feet of the workman who arranges it, three unshod horses are put upon the floor, or three two-year-old colts. These are trotted circularly around a man who occupies the centre, and who holds them by a rein. After they have been round several times, the colza is turned with hayforks, and the horses brought on again. In this way the thrashing is done very quickly. If a very large crop, two thrashing-flours should be made, so that when one bed is preparing, another may be thrashing and emptying. After being thrashed, the seeds may be housed, either in the chaff or partially screened through ridges. When put into granaries, the colza should be spread in small beds, and turned frequently for some time, being subject to heating, by which much of their value is lost. It should only be completely cleaned when perfectly dry, or when it is desirable to sell, as it keeps so much better when mixed with more or less chaff. It is scarcely necessary to observe that colza may be thrashed by means of the common thrashing machines used for grain.

Spring Colza.—In clayey and new soils, the spring colza is generally more productive than the rape, yet it is always a very uncertain crop, like all leguminous and oily grains which are sown in the spring. It is one of the most profitable plants that can be grown in the soils of newly-drained ponds and meadows. Some persons, however, have obtained abundant crops from ground adapted to the growth of
wheat, but this has been in particularly favourable seasons.

The spring colza should not be sown as late as the rape, as its growth is much slower. "In one very favourable year," says Dombasle, "when I had sown colza on the 2d of June, it did not arrive at maturity soon enough to admit of being harvested."

After the soil has been well prepared by two or three ploughings, the seed may be sown broad-cast, at the rate of 7 or 8 lbs. per acre on very light ground, covering it with the harrow. Some sow the colza in drills eighteen inches apart, and till between the rows with a horse-hoe. But, in general, cultivation, which is so beneficial to winter colza and rape, produces but a poor effect on a crop which occupies the soil so short a time.

COMFREY, COMMON (Symphytum officinale). This wild plant grows by the sides of ditches and in moist places to a height of three feet. The leaves are a deep green colour, pointed, long, and rough to the touch. The stalk is green, thick, and upright, and winged at the bases of the leaves. The flowers are sometimes white, and often reddish in colour. The root is thick, black externally, and white internally. It is full of a sticky juice when crushed or broken. The root is the part used medicinally. It contains much mucilage, and may be used as a demulcent. Conserve of comfrey is the best way of preserving it through the year. The tuberous-rooted comfrey (S. tuberosum) is an herb of much humbler stature than the last-named root; knobbed and branched; externally whitish; flowers fewer, drooping, yellowish-white, tinged with green. (Smith's Eng. Flora, vol. i. p. 203.)

The prickly comfrey (S. asperum) is a hardy perennial of gigantic growth, introduced from Caucasus as an ornamental plant, in 1811, by Messrs. Lodigies of Hackney. (See Curtis's Bot. Mag., No. 929.) The attraction of the agriculturalist has recently been directed to the cultivation of comfrey as green food for cattle, by Mr. Grant, of Lewisham, who speaks highly of its merits. (Baxter's Agr. Lib.)

COMPOSITION FOR TREES. See CANKER.

COMPOST (Fr.; Lat. composition). That sort of manure which is formed by the union or mixture of one or more different ingredients with dung, or other similar matter. An excellent essay, by Mr. James Dixon, on making compost heaps from liquids and other substances, written on the evidence of many years' experience, was awarded a premium of 10l. in July, 1839, by the Royal Agr. Soc. of England, and is published in their Quart. Journ. vol. i. p. 135. See also FARM-YARD MANURE.

CONDITION (Fr. and Lat.). In horsemanship, a term supposed to imply a horse's being in a state of strength and power, so much above the purpose he is destined to, that he displays it in his figure and appearance: this, according to Taplin, signifies "fine in coat, firm in flesh, high in spirits, and fresh upon his legs."

CONFIDENT PLANTS AND TREES. Such plants and trees as bear cones; as the fir, pine, cedar, &c.

CONSERVATORY (Lat.). A glazed structure, in which exotic trees and shrubs are grown in a bed or floor of soil. It is distinguished from an orangery by its having a glazed roof, while that of the latter is opaque, and from a greenhouse by the plants being set in the open soil, instead of in pots placed on shelves. The largest conservatory in the world at the present time (close of 1841), is that erected in Chatsworth, in Derbyshire, for palms and other tropical plants, which covers above an acre of ground, and is sixty feet high. (Braudel's Dict. of Science and Art.)

CONTRACTION OF THE HOOF. In farriery, is a distorted state of the horny substance of the hoof in cattle, producing all the mischiefs of unnatural and irregular pressure on the soft parts contained in it, and consequently a degree of lameness which can only be cured by removing the cause. Contraction of the hoof rarely happens, however, except to those animals whose hoofs, for the convenience of labour, are shod.

CONVERTIBLE HUSBANDRY, or mixed husbandry, a term implying frequent change in the same field from tillage crops to grass, and from grass back to tillage crops; an alternation of wheat, rye, &c., with root and grass crops.

COOP, or Coup (Icel. knoppa; Dut. knappe). A provincial name for a tumbrel or cart, enclosed with boards to carry dung, sand, grains, &c. It is also a pen or enclosure where lambs, &c., are shut up to be fed or fattened; and a kind of cage in which poultry are enclosed for the same purpose.

COPPICE, or COPSE (supposed from the Fr. cooper; or Nor. copper, to cut off). Low woods cut at stated times for poles, fuel, &c. A place overrun with brushwood. Its wood is called coppice-wood.

CORDGRASS (Spartina stricta). From spartina, a rope made of broom. A genus of perennial maritime grasses found in muddy salt marshes on the sea coast, of which this is the only native variety. They are very easy of culture, and increased by divisions and seeds. Roots, creeping, with strong fibres; whole plant, hard, tough, and rigid; stems ten to twenty inches high, several together; leaves, numerous, towel-like, differentiated of a dull green colour and smooth. (Eng. Flora, vol. i. p. 135; Paxton's Bot. Dict.)

Spartina juncea.—According to the experiments of Sinclair, this grass is very late in the production of foliage, and inferior in nutritive qualities to most other kinds of grass. It, however, yields well as a single crop, the produce from a rich, silicious, sandy soil, at the time of flowering, being 33,350 lbs., which afforded of nutritive matter 1433 lbs. It has been tried for the purpose of forming into flax; and Sinclair tells us, the results were favourable, inasmuch as the clear fibre was equal in strength and softness to that of flax, but it was deficient in length. The only advantage that appears would result from this plant affording flax is, that it could be produced on a soil unfit for the growth of flax or the production of corn. It flowers the second week in August, and the seed is ripe by the middle of September. (Hort. Gram. Web. p. 373.) Three or four species of
CORD-WOOD. Sparina are found in the United States, chiefly confined to the salt water districts along the sea coast, and CORD-WOOD. Small pieces of wood broken up for fuel. It also signifies top-wood, roots, &c., cut up and set in cords; so deno-
minated from its being formerly measured with a cord. A statute cord of wood should be eight feet long, four feet high, and four feet broad.

COREOPSIS, EAR-LEAVED, (Coropsis auriculata.) A hardy perennial, a native of North America. It grows three or four feet high, and its yellow flowers bloom in August. The Cor-
reopsis is also a native of North America, growing about eighteen inches high, with yellow flowers. Blooms from July to October. Divide the roots, and plant it in open situations.

CORIANDER, (Coriandrum sativum. From σατιβομ, a bug; the fresh leaves, when bruised, emitting an odour very similar to that of this vermin). Coriander thrives best in a moderate rich but sandy loam: excessive moisture is equally inimical to it as the want of a regular supply. It must have an open and rather sheltered situation. It is propagated by seed, which, if it is required early, must be sown during February, in a warm border or moderate hothot, in either situation with the protec-
tion of a frame. This may be repeated at the close of March. Afterwards small crops may be successively inserted every month in an open bed or border until September, in which month, and October, if required for winter's supply, final crops must be sown under a frame; and in February. The summer sowings should always be of small extent, as the plants at that season are very apt to run.

The sowings are generally performed in drills eight inches apart, and half an inch deep; the plants to remain where sown. The only cultivation required is to thin them to four inches' distance and to have them kept clear of weeds throughout their growth. For the production of seed, some plants of the early spring sowings must be left ungathered from, at about eight inches apart each way; they will perfect their seed in early autumn, being in flower during June. (G. W. Johnson's Kitchen Garden.)

CORK OAK (Quercus suber). The tree pro-
ducing the thick, light, and soft bark, out of which corks are made, is a species of oak found in the southern parts of Europe, in Spain, France, and Italy. Both public and private interest, says Michaux, requires the in-
habitants of the southern coast of the United States, and in February, of the neighbouring islands, to introduce and rear the cork oak, in places unfit for the culture of cotton. It should also, he thinks, be introduced into West Ten-
nessee, and with the more reason as the vine is there cultivated successfully. It will grow wherever the live oak is found.

In size this oak seldom grows higher than forty feet, with a diameter of three feet. Its leaves are evergreen, but the greater part of them fall and are renewed in the spring. The acorns are large and oval, of a sweetish taste, and eagerly devoured by swine. The wood is hard, compact and heavy, but not so durable as that of some other kinds of oak. The bark begins to be taken off at the age of twenty-five years, the first growth being of little value. It is not, however, till the tree is forty-five or fifty years old, that the bark possesses all the qual-
ties requisite for good corks, and from that pe-
tiod it is collected every eight or ten years.

The length of time which thus elapses between planting and reaping compensation renders it very improbable that the cork oak will ever be extensively introduced by individual enter-
prise, into those parts of the United States where it would thrive. Nothing short of go-
gernment patronage could effect the object re-
commended by Michaux. The consumption of corks is exceedingly great; in France alone it amounts annually to 125 or 150,000,000.

CORN. A term which in Europe is applied alike to wheat, barley, and the other small grains, whilst in the United States it is used almost exclusively to designate Indian corn or maize.

CORN BINDWEED. See BINDWED.

CORN, BROOM. The following account of the broom-corn, its culture and uses, is the substance of a communication made by Mr. William Allen of Northampton, Massachusetts, to Mr. H. L. Ellsworth, Commissioner of Pa-
tents.

Of the genus sagrwm (broom-grass) there are four or five species. Sorghum saccharatum is the broom-corn, abundantly cultivated in this country, both for the seed and for its large panicles, which are made into the brooms. The whole plant is saccharine. Attempts have been made in France to extract sugar from it, but with little success.

The other species are the following: Sor-
ghum dora (or holcus dora), common Indian millet, a native of the East Indies, but culti-
ivated in the south of Europe; S. bicolor, or two-
coloured Indian millet; S. caffrwm, caffres Indian millet, and S. nigrwm, coal-black Indian millet.

Of the sorghum saccharatum (or holcus sacca-
rahum), broom-corn there are several varieties raised in Hampshire country, Massachusetts, in the valley of the Connecticut river, prin-
cipally in the broad meadows of Northampton, Hadley, and Hatfield. The pine tree kind is regarded as the poorest kind, or the least advan-
tageous for cultivation; yet, as it is the earliest (being three weeks earlier than the large kind), in a short season, when its seed will ripen, while the seeds of the other kind fail to ripen, this may prove the most profitable crop. The North river crop is ordinarily the best crop; it is ten days earlier than the large kind, and yields about 750 lbs. of the brush per acre—
the brush meaning the dried panicles, cleaned of the seed, with eight or twelve inches of the stalk. The New Jersey, or large kind, yields a thousand or one hundred pounds of brush per acre. The stalks and seed are large. In good seasons, this is the most profitable crop. But in the present season (1842), owing to an early frost (about September 23), much of the seed of this kind will fail to ripen. There is also the Shirley, or black brush. Still rich, alluvial lands are best adapted for the broom-
CORN, BROOM.-

Corn, more especially if warmly situated, protected by hills, and well manured.

Method of planting.—The broom-corn is planted in rows, about 3 or 3 feet apart, so that a horse may pass between them with a plough, or cultivator, or harrow. The hills in each row are from 18 inches to 2 feet apart, or farther, according to the quality of the soil. The quantity of seed to be planted is estimated very differently by different farmers—some say that half a peck is enough per acre, while others plant half a bushel, and some a bushel, in order to have that the stalks shall be well stocked. The rule with some is to cast a teaspoonful, or 30 or 40 seeds, in a hill; the manner at the time of planting should be put into the hill, and old manure or compost is preferred, as being most free from worms.

Cultivation.—The broom-corn should be ploughed and hoed three times—the last time when about three feet high, though some hoe it when it is six feet high, and when they are concealed by it as they are toiling in the field. The number of stalks in a hill should be from seven to ten. If there are only five or six stalks, they will be larger and coarser; if there are about eight, the brush will be finer and more valuable. In the first hoeing, the supernumerary stalks should be pulled up.

Harvesting.—As the frost kills the seed, the broom-corn is harvested at the commencement of the first frost. The long stalks are bent down at 3 or 2½ feet from the ground; and by laying those of two rows across each other obliquely, a kind of table is made by every two rows, with a passage between each table, for the convenience of harvesting. After drying for a few days, the brush is cut, leaving of the stalks from 6 to 12 inches. The longer it is cut, of course, the more it will weigh; and, if the purchaser does not object, the benefit will accrue to the farmer. However, the dry stalk weighs but little; if its weight is excessive, the purchaser sometimes requires a deduction from the weight. As it is cut, it is spread on the tables, still farther to dry. As it is carried into the barn, some bind it in sheaves; and this is a great convenience for the further operation of extracting the seed. Others throw the brush into the cart or wagon, unbound.

Scraping.—The process of extracting the seed is called “scraping the brush.” Two iron horizontal scrapers are prepared—one movable, to be elevated a little, so that a handful of brush may be introduced between them. The upper scraper is then pressed down with one hand, and the brush drawn through with the other, the seed being scraped off. This is the old method. A newly invented scraper is superseding the old one. It is an upright instrument, of elastic wood or steel, inserted in a bench of a convenient height for the operator.

The form is as follows:

a is a piece of wood or steel, immovable; b and c are ribs which are elastic, movable to the right and left at the top, but fastened to the central piece below. The degree of elasticity may be regulated by wedges in the planks d and f—wedges in the hole through which the pieces pass.

A quantity of brush is taken in the hand, and brought down upon the top of this instrument. As it is forced down, and drawn towards the body, it separates the elastic sticks from the central piece, but their elasticity presses sufficiently on the brush, so that the seed is scraped off.

The advantage of this scraper is, that both hands may be applied to the brush, instead of only one hand, as in the other kind, and the elastic power of nature is substituted for the pressure of one of the hands. The instrument also seems to double the scraping surface. The instrument was invented at Hartford. I have been told it has not been patented.

The following plan may therefore be useful. The operator stands at the end A.

The lower plank may rest on the barn floor, or have short legs. The upper oblique has a hole, through which the scraper passes, and down which the seed may fall. Each side of the instrument, a wedge may be applied, to regulate its elasticity, or by some other contrivance this object may be secured. In scraping, the panicles must first be laid evenly together, and the stalks taken in the hand. If this is not done in the field, and bundles not formed, then must it be done with considerable labour at the time of scraping in the barn.

Product.—A common crop is 700 to 800 lbs. per acre. There have been raised 1000 and 1100 lbs. per acre, with 80 to 100 bushels of seed. The large kind grows eleven feet high.

Value of the crop.—About the year 1836 or 1837, the brush sold for 12½ cents a pound; and one farmer in Northampton sold his crop standing, unharvested, at $100 per acre. Since then, the price has been decreasing. This year it has been 4 and 5 cents. At 6 cents, the farmer, for 800 lbs., gets $48 an acre, besides 60 or 70 bushels of seed, worth a third of a dollar a bushel—so that he receives $70 or upwards from an acre.

Good farmers regard the seed alone as equal to a crop of oats from the same land. Some land owners have rented their land for broom-corn, at $25 per acre, they putting on five or six loads of manure.

One farmer, who, a few years ago, cultivated 50 acres in broom-corn, must have had an almost unequaled income for a New England farmer.

Quantity.—In Northampton, probably 200 acres are raised; in Hatfield, 300; in Hadley, 400; in other towns, Whately, Deerfield, Greenfield, Easthampton, Southampton, South-Hadley, Springfield, and Longmeadow, perhaps 300 or 400 acres more; in all, in the valley of
CORN CALE.

the Connecticut, 1200 or 1300 acres; the product, in brush and seed, worth $1,000,000.

Manufacture of brooms.—Individuals tie up brooms with wire or twine. The expense is greater for materials and labour when wire is used.

The turned broom handles cost, as delivered, only one dollar a hundred—one cent each. The expense of other materials and labour in making a broom is 6 cents, or on the whole about 7 cents. In a good broom a pound and a half of brush is employed, which at the present price of 5 cents, would be 31/2 cents, so that a broom made with wire costs now about 141/2 cents. A manufacturer recently went to Boston, and could get an offer of only 12 cents, or $12 per hundred, for his brooms; at which rate he could not afford to sell them and chose to retain them. Brooms are made with brush weighing 3/4 of a pound, 1 pound, 11/4 pound, and 11/2 pound. The brush is whitened by the manufacturer. It is placed in a large tight box, and bleached by the fumes of sulphur; but this process is said to weaken the brush. Who would think of whitening broom brush, for beauty! Thus it is that fashion descends into the vale of life, and to the humblest of concerns. Why should not the housemaid wield a beautiful broom, with white brush and variously interlaced wire, and polished and variously coloured handle?

Miscellaneous.—A few remarks will be added, some of which were omitted in their proper places. If the stalks are cut before the seed is ripe, they are better, stronger, more durable, than if cut after the seed is ripe. In this case, the farmer would lose the value of the seed. He of course will not submit to this loss, unless it is made up to him by the increased price of the brush.

The seed is used for feeding horses, cattle, and swine. It is ground and mixed with Indian meal, and is regarded as excellent food— it weighs forty pounds a bushel.

Mr. Shipman of Hadley is the greatest manufacturer of brooms in the valley of the Connecticut. If he employs, on an average, ten hands, and each hand makes 25 brooms per day, the number made in a year would be 78,000. It is said he has made 100,000.

The brush, when it is put in the barn, should be placed on a scaffold, so as to be exposed to a circulation of the air, that it may dry and not mould. For all the purposes of use, a broom made with twine is equal to one made with wire; and a man can make several more of them in a day.

Mr. Shipman uses 300 or 400 lbs. of large twine, at 20 to 30 cents a pound, and 2,000 lbs. of small twine, at 31 cents. Perhaps he manufactures only 1/4 part of the brooms manufactured in Hadley. At the price of 20 cents, the price of brooms a few years ago, the broom manufacturer of Hadley would thus amount to $160,000.

It is probable that the extended cultivation of the broom-corn will reduce the profits on this product to the average profits of good farming.

CORN CALE. A provincial name for charlock.

CORN-CROWFOOT (Ranunculus arvensis).

CORN LAWS.

A weed very common among corn. Root fibrous. It has an upright stalk; the leaves are of a pale, shining green, and cut into long, narrow, acute segments. The lemon-coloured flowers are much smaller and paler than those of the common crowfoot, which is found in pastures and meadows, and the seed-vessels are very remarkable, being covered all over with prickles. It is very acrid and dangerous to cattle, though they are said to eat it greedily. M. Bragdon, who has given a particular account of its qualities, relates, that three ounces of the juice killed a dog in four minutes. (Smith's Engl. Flor. vol. iii. p. 53.) See Crowfoot.

CORN-CUTTING MACHINES. Machines for cutting wheat and other grains by horse power, of which none have hitherto been produced in England whose merits have insured their adoption by the farmer. Of the several English patents obtained, that called Smith's Reaping Machine, is perhaps the most approved. For a minute description of this, with drawings, see Encyc. Britannica, vol. 2, part 1. See Mowing and Reaping Machine.

CORNEL TREE. See Dogwood.

CORNET. In farriery, a name sometimes given to the instrument used in venesection, called a fleam.

CORN, INDIAN. See MAIZE.

CORN LAWS. The regulation of the supply, and consequently, the value of corn in different countries in Europe, has been an object of legislation from a very remote period; a public interference, varying, however, in degree, from that of protective taxation, to that which was intended to be prohibitory. Of the first kind are the modern English corn laws; of the last are the present local regulations of Paris, by which bread is sold always at the same price, both in bountiful seasons or in those of scarcity. It would occupy too much space to follow these, generally necessary interferences with the sale of corn, which have occurred from the days of the Athenians (who depended upon Thrace for their daily bread), or from the popular broils about bread, which were long a cause of disorder to Rome, even in its splendid. In England, there are traces of a corn law nearly six centuries since. By the statute Judicium Pillorie, 51 Hen. 3 (1268), it is directed that the municipal authorities of certain towns should inquire of the price of corn. By the 3 Ed. 3, c. 20 (1360), the exportation of corn was prohibited; but in 1436, by the 15 H. 6, c. 2, it was allowed. In 1463, however, by the 3 Ed. 4, c. 2, the necessity (which was declared in the preamble) arose of preventing "the labourers and occupiers of land from being grievously endamaged by bringing corn out of other lands when corn of the growing of this realm is at a low price." It then declares that wheat shall not be import ed, unless wheat be sold at the place of import for 6s. 3d. per quarter. In 1532, by the 25 H. 8, c. 2, it was enacted that the exportation of corn should cease, and the price be regulated by the lords of the council, the preamble of the bill very sensibly remarking, that "death, scarcity, good and cheap and plenty of, &c., victuals necessary for man's sustenance happeneth, riseth, and chanceth of so many and
In 1534 (1 P. & M. c. 5), corn was again allowed to be exported when the price of wheat did not exceed 6s. 8d. per quarter. This standard was increased to 10s. by the 5 Eliz. c. 5 (1562); and in 1571 (13 Eliz. c. 13), the exportation was directed to be regulated from average prices by the lords of the council. In 1607, the bounty upon the exportation of grain finally ceased.

According to the English Corn Law Act, existing in 187 towns, to transmit returns to the Board of Trade, who compute the average weekly price of each description of grain, and the aggregate average price for the previous six weeks, and transmit a certified copy to the collectors of customs at the different ports. The aggregate average regulates the duty on importation according to the following scale:

If imported from any Foreign Country.

CORN MARYGOLD (Chrysanthemum segetum). In Scotland, this is called yellow gowens, quills, goels; in Kent, England, yellow bottle; in Norfolk, buckland; midland counties, golds, goolds, or goels; north of England, gowens, goldens, guls.

CORN MOTH (Tinea granella). Among the insects most injurious in their attacks on grain, when laid up in magazines, is the larve of this small moth (the mothed woolen moth of Harworth), the caterpillar of which is also called in England the white corn worm. The perfect moth measures, from the head to the tips of the wings, six or seven lines. The insect appears in that country as a moth in May, June, and July. It frequents granaries and other buildings where grain is stored, sits at rest in the day-time, and only flies about at night. It is in the summer months, from May to August, and sometimes in September, that the larve devour the different sorts of grain; and they attack rye, oats, and barley, with the same zest as wheat. From September to May the larve is sought for in vain in the corn-heaps; it has retired into the cracks and fissures of the floor and walls, and moreover has concealed itself in its cocoon. It does not reappear till April or May, and then in a very different form; namely, as a moth, which flutters about the heaps of store-corn, and deposits upon them the invisible germ of future destruction. After a few days

555
have elapsed, small whitish worm maggots, or more properly speaking larve, proceed from the eggs, and immediately penetrate into the grain, carefully closing up the opening with their white roundish excrement, which they glue together by a fine web.

"The European grain-moth (Tineca granella), in its perfected state, is," says Dr. Harris, "a winged insect, between three and four-tenths of an inch long from the head to the tip of its wings, and expands the sixth of an inch. It has a whitish tuft on its forehead; its long and narrow wings cover its back like a sloping roof, are a little turned up behind, and are edged with a wide fringe. Its fore-wings are glossy like satin, and are marbled with white or gray, light brown, and dark brown or blackish spots, and there is always one dark square spot near the middle of the outer edge. Its hind wings are blackish. Some of these winged moths appear in May, others in July and August, at which times they lay their eggs; for there are two broods of them in the course of the year. The young from the first laid eggs come to their growth and finish their transformations in six weeks or two months; the others live through the winter, and turn to winged moths in the following spring. The young moth-worms do not burrow into the grain, as has been asserted by some writers, who seem to have confounded them with the Angoumois grain-worms; but, as soon as they are hatched, they begin to gnaw the grain and cover themselves with the fragments, which they line with a silken web. As they increase in size they fasten together several grains with their webs, so as to make a larger cavity, wherein they live. After a while, becoming uneasy, in their confined habitations, they come out, and wander over the grain, spinning their threads as they go, till they have found a suitable place wherein to make their cocoons. Thus, wheat, rye, barley, and oats, all of which they attack, will be found full of lumps of grains cemented together by these corn-worms, as they are sometimes called; and when they are very numerous, the whole surface of the grain in the bin will be covered with a thick crust of webs and of adhering grains. These destructive corn-worms are really soft and naked caterpillars, of a cylindrical shape, tapering a little at each end, and are provided with sixteen legs, the first three pairs of which are conical and jointed, and the others fleshly and wart-like. When fully grown, they measure, as some writers have estimated, an inch and a quarter in length, and are of a light ochre or buff colour, with a reddish head. When about six weeks old they leave the grain, and get into cracks, or around the sides of corn-bins, and each one then makes itself a little oval pod or cocoon, about as large as a grain of wheat. The insects of the first brood, as before said, come out of their cocoons, in the winged form, in July and August, and lay their eggs for another brood: the others remain unchanging in their cocoons, through the winter, and take the chrysalis form in March or April following. Three weeks afterwards, the shining brown chrysalis forces itself out of the cocoon, by the help of some little sharp points on its tail, and bursts open at the other end, so as to allow the moth therein confined to come forth.

"The foregoing account will probably enable the readers of this essay to determine whether these destructive insects are found in our own country. From various statements, deficient however in exactness, that have appeared in some of our agricultural journals, I am led to think that this corn-moth, or an insect exactly like it in its habits, prevails in all parts of the country, and that it has generally been mistaken for the grain-weevil, which it far surpasses in its devastations. Many years ago I remember to have seen oats and shelled corn (maize) affected in the way above described, and have observed seed-corn, hanging in the ears, to have been attacked by insects of this kind, the empty chrysalids of which remained sticking between the kernels; but, for some time past, no opportunity for further investigation has offered itself.

"There is another grain-moth, which, at various times, has been found to be more destructive in granaries, in some provinces of France, than the preceding kind. It is the Angoumois moth (Anacampsis cereallic). The winged moths of this group have only two visible feelers, and these are generally long, slender, and curved over their heads. Their narrow wings most often overlap each other, and cover their backs horizontally when shut. The Angoumois grain moth probably belongs to the modern genus Anacampsis, a word derived from the Greek, and signifying recurved, in allusion to the direction of the feelers of the moths. In the year 1769, Colonel Landon Carter, of Sabine Hall, Virginia, communicated to the American Philosophical Society at Philadelphia, some interesting observations concerning the fly-weevil that destroys wheat. These were printed in the first volume of the 'Transactions' of the Society, and were followed by some remarks on the subject by 'the Committee of Husbandry.' It is highly probable that this fly-weevil is no other than the destructive Angoumois grain-moth; for Colonel Carter's account of it, though deficient in some particulars, agrees essentially with what has been published respecting the European insect. Mr. E. C. Herrick has recently sent me, from New Haven, Connecticut, some wheat, that has been eaten by moths precisely in the same way as grain is attacked by the Angoumois grain-moth; and a gentleman to whom this moth-eaten wheat was shown, informed me that he had seen grain thus afflicted in Maine. Unfortunately the insects contained in this wheat were dead when received, having perished in the chrysalis state; had they lived to finish their transformations, I have good reason to think that they would have proved to be identical with the Angoumois moths. The following particulars respecting the latter are chiefly gathered from Reamur's 'Mémoires,' and from a work by Duhamel du Monceau and Tillet, who were commissioned by the Academy of Sciences of Paris, in the year 1760, to inquire into the nature of the insect, on account of its ravages in Angoumois, a part of France where
CORN MOTH.

CORN SALAD.

It had long been known, and had multiplied to an alarming extent. The Angoumois moth, or Anacronis cerebella, in its perfect state, is a four-winged insect, about three-eighths of an inch long, when its wings are shut. It has a pair of tapering curved feelers, turned over its head. Its upper wings are narrow, of a light brown colour, without spots, and have the lustre of satin; they cover the body horizontally above, but droop a little at the sides. The lower wings and the rest of the body are ash-coloured. This moth lays its eggs, which vary in number from sixty to ninety, in clusters, on the ears of wheat, rye, and barley, most often while these plants are growing in the field, and the ears are young and tender; sometimes also on stored grain in the autumn. Hence it appears that they breed twice a year; the insects from the eggs laid in the early part of summer, coming to perfection and providing for another brood of moth-worms in the autumn. The little worm-like caterpillars, as soon as they are hatched, disperse, and each one selects a single grain, into which it burrows immediately at the most tender part, and remains concealed therein after the grain is harvested. It devours the mealy substance within the hull; and this destruction goes on so secretly, that it can only be detected by the softness of the grain or the loss of its weight. When fully grown this caterpillar is not more than one-fifth of an inch long. It is of a white colour, with a brownish head; and it has six small jointed legs, and ten extremely small wart-like proplegs. Duhanel has represented it as having two little horns, just behind the head, and two short bristles at the end of its tapering body. Having eaten out the heart of the grain, which is just enough for all its wants, it spins a silken web or curtain to divide the hollow, lengthwise, into two unequal parts, the smaller containing the rejected fragments of its food, and the larger cavity serving instead of a cocoon, wherein the insect undergoes its transformations. Before turning to a chrysalis it gnaws a small hole nearly or quite through the hull, and sometimes also through the chaff covering of the grain, through which it can make its escape easily when it becomes a winged moth. The insects of the first, or summer brood, come to maturity in about three weeks, remain but a short time in the chrysalis state, and turn to winged moths in the autumn, and at this time may be found, in the evening, in great numbers, laying their eggs on the grain stored in barns and granaries. The moth-worms of the second brood remain in the grain through winter, and do not change to winged insects till the following summer, when they come out, fly into the fields in the night, and lay their eggs on the young ears of the growing grain. When damaged grain is sown, it comes up very thin; the infected kernels never sprout, but the insects lodged in them remain alive, finish their transformations in the field, and in due time come out of the ground in the winged form.

"It has been proved by experience that the ravages of the two kinds of grain-moths, whose history has been now given, can be effectually checked by drying the damaged grain in an oven or kiln; and that a heat of one hundred and sixty-seven degrees, by Fahrenheit's thermometer, continued during twelve hours, will kill the insects in all their forms. Indeed, the heat may be reduced to one hundred and four degrees, with the same effect, but the grain must then be exposed to it for the space of two days. The other means, that have been employed for the preservation of grain from these destructive moths, it is unnecessary to describe; they are probably well known to most of our farmers and millers, and are rarely so effectual as the process above mentioned." (Harrie's Treatise on Insects.)

From these considerations, the means which the agriculturist must employ to secure his grain from so dangerous an enemy, are clearly deducible. First of all, the lofts, before the corn is placed in them, must be carefully examined, and the cocoons, if any are discovered, got rid of. Sprinkling the floor with a mixture of strong white wine vinegar and salt, before laying up the corn, is strongly recommended. Sweeping the floor and walls thoroughly should not be neglected; and the dust should be removed immediately, in order that the larvae may not find their way back into the corn-heaps. Common salt will also purify the infested grain. One of the surest remedies appears to be a free ventilation, by means of an artificial degree of cold, as the larvæ can only live in a temperature of 55° to 60° of Fahr. Oats and spiders are the principal natural enemies of the corn-moth, and some small birds also feed on them. See Grain Weevil. (Treatise on Insects, &c., by J. and M. Loudon.)

CORN POPPY (Papaver rhoeas). Pl. 10, s. Indifferently called red-poppy, corn rose, copenhagen, head-wark, red-weed, red-mailkes, &c. A troublesome weed in corn fields. Annual, flowering from June to July. Beautiful varieties of this species, with semi-double flowers, variegated with rose-colour and white, are easily cultivated for ornament, but liable to degenerate in luxuriance. (Smith's Eng. Flor. vol. iii. p. 11; Sinclair's Weeds, p. 46.) See Poppy, Field.

CORN SALAD, or LAMB'S LETTUCE (Fedia olitoria, Smith; Faleria locusta, Lin.). A well-known annual weed in corn fields and light cultivated ground, which probably took its common English name from the circumstance of the plants appearing in flower about the time that lambs are dropped. There is a second species (F. dentata), oval fruited corn salad. The common variety is cultivated for winter and spring salads, and for this purpose has been long known. The first dish formerly brought to table was a red herring set in a corn salad. The plant will flourish in any soil that is not particularly heavy. It is propagated by seed, sown in February and the two following months, and once a month during the summer; but it is not so palatable during this season. Lastly, during August and early in September, the plants from which will be fit for use in early spring, or during the winter if mild. The seed may be sown in drills six inches apart, or broadcast, and raked in. Keep them free from
CORN WEEVIL.

weeds by frequent hoeings, previously thinned to four inches asunder. They should always be eaten quite young. In summer, the whole plant may be cut, as it soon advances to seed at this season; but in spring and winter the outer leaves only should be gathered. For the production of seed some of the spring-raised plants must be left ungathered. They flower in June, and perfect their seed during the two following months. (G. W. Johnson's *Kitch. Gard.; Smith's *Eag. Flor.* vol. i. p. 44; *Sinclair's Weeds*, p. 54.)

CORN WEEVIL (Calandra granaria, Clairville; Curculio granaria, Linn.). This is another extremely injurious insect to grain. See Grain WEEVIL.

CORN, IN HORSES' FEET. This disease is produced by some hard substance pressing on the sole at the quarters, as from shoes left on till the heels become buried in the hoof; the fibrous substance which lies between the sensible foot and the absolute horny hoof becomes inflamed by the pressure, and the inflammation produces a hardness of the spot, similar, if I may so express it, to a knot in a piece of soft timber. Palliate the evil as well as you can, by keeping the hoof constantly pared away between the corn and the ground, but do not wound in your vain endeavours to cut it out; avoid the hot irons, &c.; let a bit of sponge be softly put in, merely to keep out gravel and keep the spot moist; and when the season arrives, turn the horse out without any shoes, into a soft marshy place, where his feet must be in a constant moist state for three months at least: by that time the hoof will be altogether renewed, the diseased part will have grown out, and if there is no new injury, there will be no new corns. (E. Manweller. See also, Lib. use know. The Horse, p. 305.)

CORNET-BONE. The second of the consolidated phalanges of the horse's foot.

COSSEART, or CossSet (R. casscio, from case, the house). A lamb leapt by the death of its dam before it is capable of providing for itself; or a lamb taken from a ewe that brings more than one. The term is also applied to a colt, calf, &c. and sometimes written cot-lamb.

COSTIVENESS. In farriery, a complaint to which horses are often subject, occasioned sometimes by violent or hard exercise, especially in hot weather; and at other times by standing long at hard meat without grass or other cleansing diet, and with very little exercise.

COTTAGES. These for labourers are commonly constructed merely with a regard to economy; the comfort and health of their future tenants being too often disregarded. Such cottages should never consist of less than two bedrooms, and a kitchen, and outhouse. They will be found to be considerably more healthy with wooden floors, raised above the level of the surrounding ground. They should be well furnished with windows, and the ceilings of the rooms of a fair height, eight or nine feet will not be too much, to allow them to have as good gardens as possible. The plans for their formation, and the materials of which they are composed, must vary with the locality. Mr. Gillespie has given one for a cottage with a roof without wood, which he asserts could be built in Scotland for 30l. (Com. *Board of Agr.* vol. iv. p. 469.) There is also an essay by Mr. Smith, on cottages for the labouring classes, which may be consulted with advantage (Trans. High. Soc. vol. iv. p. 205), and on cottage windows (Quart. *Journ. of Agr.* p. 116), and also on cottage premiums, and on the cottages built on the estate of Lord Roseberry. (Trans. High. Soc. vol. vi. p. 527.)

By the erection of small, comfortable cottages on poor waste lands, and the allotment to each of a few acres of land, a field is opened for the rapid recovery by the spade of barren lands, and the profitable employment of the landowner's capital, too little understood. By merely deepening and mixing the soil, the cottager can bring into cultivation lands, which seem to defy all the powers of even the subsoil plough.

The following information relative to the best modes of building cheap cottages is from a report made to Congress by Henry L. Ellsworth, see pp. 55—57.

"After selecting a suitable spot of ground, as near the place of building as practicable, let a circle of ten feet or more be described. Let the loam be removed, and the clay dug up one foot thick, or, if clay is not found on the spot, let it be carted in to that depth. Any ordinary clay will answer. Tread this clay over with cattle, and add some straw cut six or eight inches long. After the clay is well tempered with working it with the cattle, the material is duly prepared for the making of brick. A mould is then formed of plank, of the size of the brick desired. In England, they are usually made eighteen inches long, one foot wide, and nine inches thick. I have found the more convenient size to be one foot long, seven inches wide, and five inches thick. The mould should have a bottom. The clay is then placed in the mould in the same manner, and brick moulds are ordinarily filled. A wire or piece of iron hoop will answer very well for striking off the top. One man will mould about as fast as another can carry away, two moulds being used by him. The bricks are placed upon the level ground, where they are suffered to dry two days, turning them up edgewise the second day, and then packed up in a pile, protected from the rain, and left to dry ten or twelve days, during which time the foundation of the building can be prepared. If a cellar is desired, this must be formed of stone or brick, one foot above the surface of the ground. For cheap buildings on the prairie, wood sills, twelve or fourteen inches wide, may be laid on piles or stones. This will form a good superstructure. Where lime and small stones abound, grout made of those materials (lime and stones) will answer very well.

"In all cases, however, before commencing the walls for the first story, it is very desirable, as well in this case as in walls of brick, to lay a step course of slate; this will intercept the dampness so often rising in the walls of brick houses. The wall is laid by placing the brick lengthwise, thus making the wall one foot thick.
Ordinary clay, such as is used for clay mortar, will suffice, though a weak mortar of sand and lime, when these articles are cheap, is recommended as affording a more adhesive material for the plaster. The wall may safely be carried up one story, or two or three stories; the division walls may be seven inches, just the width of the brick. The door and window frames being inserted as the wall proceeds, the building is soon raised. The roof may be shingles or thatch. In either case, it should project over the sides of the house, and also over the two ends, at least two feet, to guard the walls from vertical rains. The exterior wall is plastered with good lime mortar, and then with a second coat pebble-dashed. The inside is plastered without dashing. The floor may be laid with oak boards, slit, five or six inches wide, and laid down without jointing or planing, if they are rubbed over with a rough stone after the rooms are finished. Doors of a cheap and neat appearance may be made by taking two single boards of the length or width of the doors; placing them vertically in the space, and after the space is filled, with a narrow one on the top, with strips on the sides, and a strip in the middle. This door will be a batten door, but presenting two long panels on one side and a smooth surface on the other. If a porch or verandah is wanted, it may be roofed with boards laid with light joints and covered with a thick paper dipped in tar, and then adding a good coat, after sprinkling it with sand from a sand-box or other dish with small holes.

The article of brick built in this way are dry, warm in winter, and cool in summer, and furnish no retreat for vermin. Such houses can be made by common labourers, if a little carpenter's work is excepted, in a very short time, with a small outlay for materials, exclusive of floors, windows, doors, and roof.

The question will naturally arise, will the wall stand against the rain and frost? I answer, they have stood well in Europe, and the Hon. Mr. Poinset remarked to me that he had seen them in South America, after having been erected three hundred years. Whoever has noticed the rapid absorption of water by a brick that has been burned, will not wonder why brick walls are damp. The burning makes the brick porous, though the unburnt brick is less absorbent; but it is not proposed to present the unburnt brick to the weather. Whoevver has erected a building with merchantable brick will at once perceive the large number of soft and yellow brick, partially burned, that it contains—brick that would soon yield to the mouldering influence of frost and storms. Such brick are, however, placed within, beyond the reach of rain, and always kept dry. A good cabin is made by a single room twenty feet square. A better one is eighteen feet wide and twenty-four feet long, cutting off eight feet on one end for two small rooms, eight by nine each.

How easily could a settler erect such a cabin on the Western prairie, where clay is usually found about fifteen inches below the surface, and where stone and lime are often both very cheap? One pound of brick for chimneys is found to be quite an item of expense in wood-houses. In these mud houses no brick are needed, except for the top of the chimneys, the oven, and casing of the fireplace—though this last might be well dispensed with. A cement, to put around the chimneys, or to fill any other crack, is easily made by a mixture of one part of sand, two of ashes, and three of clay. This soon hardens, and will resist the weather. A little lard or oil may be added, to make the composition still hardier.

Such a cottage will be as cheap as a log cabin, less expensive than pine buildings, and durable for centuries. I have tried the experiment in this city by erecting a building eighteen by fifty-four feet, two stories high, adopting the different suggestions now made. Although many doubted the success of the undertaking, all now admit it has been very successful, and presents a convenient and comfortable building, that appears well to public view, and offers a residence combining as many advantages as a stone, brick, or wood house presents. I will add what London says in his most excellent work, the 'Encyclopedia of Agriculture,' pp. 74 and 75:

"The great art in building an economical cottage is to employ the kind of materials and labour which are cheapest in the given locality. In almost every part of the world the cheapest article of which the walls can be made will be found to be the earth on which the cottage stands, and to make good walls from the earth is the principal art of the rustic or primitive builder. Soils, with reference to building, may be divided into two classes: clays, loams, and all such soils as can neither be cast dry, not be burned, nor sands, and sands and gravels. The former, whether they are stiff or free, rich or poor, mixed with stones, or free from stones, may be formed into walls in one of these modes, viz., in the pisé manner, by lamps moulded in boxes, and by compressed blocks. Sandy and gravelly soils may be always made into excellent walls, by forming a frame of boards, leaving a space between the boards of the intended thickness of the wall, and filling this with gravel mixed with lime mortar, or, if this cannot be got, with mortar made of clay and straw.

"In all cases, when walls, either of this class or the former, are built, the foundations should be of stone or brick, and they should be carried up at least a foot above the upper surface of the platform.

"We shall here commence by giving one of the simplest modes of construction, from a work of a very excellent and highly estimable individual, Mr. Denson, of Waterbeach, Cambridgeshire, the author of the 'Peasant's Voice,' who built his own cottage in the manner described below:

"Mote of building the mud walls of cottages in Cambridgeshire. After a labourer has dug a sufficient quantity of clay for his purpose, he works it up with straw; he is then provided with a frame eighteen inches in length, six deep, and from nine to twelve inches in diameter. In this frame he forms his lumps, in the same manner that a brickmaker forms his bricks; they are then packed up in the weather; that done, they are fit for use, as a substitute for bricks. On laying the founda-
tion of a cottage, a few layers of brick are necessary, to prevent the lumps from contracting a damp from the earth. The fireplace is lined and the oven is built with bricks. I have known cottagers, where they could get the grant of a piece of ground to build on for themselves, erect a cottage of this description at a cost from £15 to £30. I examined one that was nearly completed, of a superior order: it contained two good lower rooms and a chamber, and was neatly thatched with straw. It is a warm, firm, and comfortable building, far superior to the one I live in; and my opinion is, that it will last for centuries. The lumps are laid with mortar, they are then plastered, and on the outside once roughcast, which is done by throwing a mixture of water, lime, and small stones, against the walls, before the plaster is dry, which gives them a very handsome appearance. The cottage I examined, cost £63, and took nearly one thousand lumps to complete it. A labourer will make that number in two days. The roofs of cottages of this description are precisely the same as when built with bricks or with a wooden frame. Cornices, gables, window and door frames, and partitions, are formed with the same materials; but in all cases the tops are covered with straw, which the thatchers perform in a very neat manner."

(Denson's Peasant's Voice, p. 31.)

**COTTAGE-CHEESE.** See **WHEY BUTTER.**

**COTTON-GRASS** (*Eriophorum. Ital. cotone; Fr. coton*). A perennial native genus of grasses, comprising seven species, which have no particular merit to warrant their recommendation for the purpose of the agriculturist; their productive and nutritive powers being very inferior. Sinclair gives us the result of his experiments on two sorts, the common long-leaved cotton-grass (*E. angustifolium*), and the hare's-tail, or sheathed cotton-grass (*E. vaginatum*).

**COTTON PLANT.** See **Gossypium.**

**COTTON TREE** (*Populus argentea*). See **Poplar.**

**COTTON-WOOD** (*Populus Canadensis*). See **Poplar.**

**COTTON, WILD** (*Jactelias Syriaca*), popularly called *silk-seed* and *swallow-wort*. An American plant growing in low grounds and on road-sides, to the height of three or four feet. (*Flora Cestrica.*)

**COTYLEDON.** The seed leaf. See **BOTANY.**

**Couch, or CREEPING WHEAT GRASS** (*Triticum repens*, Pl. 10, i.) Named from the French *coucher*, to lie down. Sometimes called *dog-grass* and *knot-grass*. Until of late years, when botanical science has afforded us better information, it was generally supposed that all couch or twitch was the roots of one species of grass. But many persons observed that some of these roots, on wet soils, were black and much smaller, and they had locally obtained the name of *black twitch*. This, on soils where it prevails, is much worse than the other, because it is wiry and small, and not so easily discharged from the soil; it is also more brittle, and by harrowing breaks short. This is the *Agrostis repens*. There are two other grasses which have strong creeping roots, and are indifferently called couch: these are the creeping-rooted soft grass (*Holcus mollis*), and the smooth-stalked meadow grass (*Poa pratensis*). There is but one way of destroying couch, and that is by ploughing up the soil and pulverizing it. (Sinclair's Weeds, p. 27.) See **AEGROSIS REPENS.** Couch or quick grass, or *creeping triticum*, is a troublesome perennial, fortunately but little known in the United States. Dr. Darlington has only been able to find it in one place, the Weston school farm, in Chester county, Pennsylvania. (See **Flora Cestrica.**)

**COUGH** (Goth. *kuef*, a catarrh; *kof*, suffocation; Dutch, *kweh*), in farriery, a convulsive motion of the lungs, being an effort of nature to throw up some offending matter from the air tubes. This is best treated, in mild cases, by cold bran washes with linseed. But coughs arise from so many different causes that it is impossible to prescribe any general remedy.

**COULTER OF A PLOUGH.** See **PLOVER.**

**COUNTER.** In horsemanship, the breast of a horse, or that part of his fore-hand which lies between the shoulders and under the neck.

**COUPLES.** A term applied to ewes and lambs. Couple is also a chain or tie that holds dogs together.

**COUPLINGS, or CUPLINGS.** Thongs of untanned leather, or other material, which are used to connect the handle or handstaff and swivel of a flail.

**COVER, or COVERT** (Fr. *couvrir*). A term applied to a place sheltered, not open or exposed. In sportsman's phrase, the cover is the chosen resort of the fox for kennelling; and such as lie high and dry are seldom without one or more, particularly if the underwood be thick and plenty. Artificial covers are often formed of broom and gorse, intermixed. (*Blaine's Rural Sports, p. 452.*)

**COVEY** (Fr. *couvere*, from the Lat. *coevus*). Provincially applied to a cover of furze, &c., for game. It is also applied to an old bird with her young ones, but is generally used to designate a number of partridges or other game.

**COW** (Sax. *cu*; Dutch, *koe*; Pers. *gou*). See **Cattle.**

**COW-BANE, WATER, or WATER HEMLOCK** (*Cicuta virosa*). A perennial, fetid, poisonous aquatic herb, found in ditches, and about the margins of rivers, not very common. Root tuberous, hollow. Stems two or three feet high, hollow, leafy, branched, furrowed. Leaves bright green, tapering at each end, from one to two inches long. Umbels large, bearing purplish flowers; fruit roundish, smooth. This is a fatal plant to cattle, if they happen to meet with it before it rises out of the water, in which state only they will eat the young leaves. (*Eng. Flor.* vol. ii, p. 62.)

**COW-BANE, SPOTTED** (*Cicuta maculata*). Water hemlock, a perennial root frequently found in low grounds and the margins of streams in Pennsylvania and other Middle States. The mature fruit of this plant is highly aromatic,—the odour something between that of aniseed and the kernels of the black walnut. The root is an active poison; and numerous lives have been lost, for want
COW-CLAGS.
of sufficient botanical knowledge to distinguish
the plant from the exorrhiza or sweet cicerly.
The herb is also destructive to cattle, when
eaten by them. There is one other species in the
United States. (Flor. Cestric.)

COW-CLAGS. A provincial name for the
cloaked lumps of dirt that hang to the buttocks
of cattle and other animals.

COW-HERD. A person whose office it is
to attend upon the herds of cows in places
where they run in common fields.

COW-HOUSE. See Cattle Shed.

COWISH. A new species of plant, called
biscuit-root, found growing on dry land in the
valley of the Columbia river. Its size is about
that of a walnut, though sometimes larger. Its
taste resembles that of the sweet potato, and it
is prepared for food by the same process as the
commas, in which state it forms a tolerable
substitute for bread.

COW-KEEPING. The business of keeping
cows for the advantage of the milk, by disposing
of the principal cow-keepers of the British metropolis have their
establishments in the suburbs, where they are
connected with pasture fields, in which their
animals are turned out a portion of every day
throughout the year, when practicable. The
cows are fed in the house with grains, mangel-
wurzel, hay, tares, &c., and as the animals get
air and exercise, the milk may be considered
wholesome. But there are other cow-keepers in
the metropolis, who confine their cows in
back houses, and even dark cells, and while
they feed them with rich food, give them no
exercise; hence, the milk of such cows cannot
be considered wholesome. (Harleian
Dairy System ; Brit. Hoeb.) See Cattle.

COW PARSNIP, or HOG WEEDE (Horo-
eolum sphenogalium). A biennial pasture weed,
which in England is found in hedges, the bor-
ders of fields, and rather moist meadows, very
common. Root tap-shaped, whitish, aromatic,
sweetish, and rather mucilaginous. Stem four
to six feet high, erect, branched, leafy, fur-
nrowed, and hollow. The leaves proceed from
a large membrane or sheath. The flowers,
which grow in large umbels, are either white
or reddish; the fruit is abundant, and light
brown. The whole plant is wholesome and
nourishing food for cattle, and is gathered in
Sussex for fattening hogs, hence its name of
hog-weed. It is also frequently known by the
name of wild parsnip, meadow parsnip, and
madrep. (Sinclair's Weeds, p. 65; Eng. Flora,
vol. ii. p. 102.)

The only ascertained species of this genus
found in the United States is the Heracleum la-
matan, or woolly cowparsnip, a perennial root,
the stem of which sometimes grows six or
eight feet high. It is frequent in low grounds
in Pennsylvania. See Flor. Cest.

COW PEA. A kind of pea much culti-
vated in the Southern States as a field crop,
and substitute for clover. See Peas.

COW-POX. In farriery, is a disease affect-
ing the teats of cows. This disease appears
in the form of small bluish vesicles surrounded
by inflammation, elevated at the edge and de-
pressed in the centre, and containing a limpid
fluid. By the use of the virus of this disease,

CRAB TREE.

has originated the present excellent system of
vaccination.

COWSLIP, AMERICAN (Dodecatheon
Meadia). A hardy perennial from South Amer-
ica, loving shade and moisture. It blows in
April and May. Propagated by seed and off-
sets. Sow the seed in pots in autumn. Plant
out the following autumn.

COWSLIP, THE COMMON, or PAIGLE
(Primula veris). A native English perennial
weed, growing in meadows and pastures,
chiefly on a clay or chalky soil. It produces
sweet-scented yellow flowers, which appear in
April, and are used for making cowslip wine
or balsamic tea. Its roots have a fine odour,
similar to that of anise, and give additional
strength to ale or beer, when immersed in the
cask. The leaves and flowers are excellent
food for silk-worms, and are eaten eagerly by
cattle. The leaves are also used as a po-
thesis, and in salads.

The flowers, leaves, and roots are all medi-
cinal portions of the cowslip, and are made
into tea, wine, and conserve. It is anodyne in
its quality, and the ancient writers upon herbs
speak highly of its effects; but their opinions
have lost their value by time. (Eng. Flora,
vol. i. p. 271; Willieth's Dom. Engr.)

COWSLIP OF JERUSALEM, or LUNG-
WORT PULMONARIA (Primula offici-
nalis). This plant is perennial and flowers in
May. It grows eight or ten inches high, with
long, broad, hairy leaves, of a deep green,
spotted on the upper side with white spots.
The stalks are slender and hairy, with small
leaves upon them. The flowers are reddish
in the bud but blue when blown, small, grow-
ing in clusters at the top of its stalk. The
root is fibrous. The leaves have been used
medicinally, from the idea that they resemble
the lungs, and therefore must be useful in dis-
ease of those organs. They are inert, and
consequently useless. Several species of
lungwort are found indigenous to the United
States.

COW-TIE. A provincial term applied to a
short thick hair rope, with a wooden nut at
one end and an eye in the other, being used for
tying the hind legs of the cows while milking.

COW-WHEAT (Melampyrum pratense). Pl.
79. A plant cultivated in Flanders for feeding
stock.

There are some species of this plant found
in the United States. One has been called by
botanists American melampyrum. This is found
in dry, hilly woodlands, and on mica-slate hills,
where it flowers in June and July. A narrow-
leaved variety is abundant in the pines of New
Jersey. (Flora Cestrica.)

CRAB TREE, or WILD APPLE TREE
(Pyrus malus). There are in England several
varieties among the wild crabs, some of which
are of excellent flavour when baked with plenty
of sugar, even surpassing cultivated apples.
(Eng. Flora, vol. ii. p. 362.) Crab apples and
sloes are the only fruits naturally belonging to
the soil, and both are medicinal. The ex-
pressed juice of any of them, called verjuice,
kept by good housewives in the country, being
excellent as an astringent gargle in sore throat
and in thrush and ulceration of the mouth and gums. It is sometimes mixed with beer-yeast, and applied outwardly, in inflammations, bad legs, burns, sprains, and scalds; but cold water and rest are better.

**CRAB APPLE** (*Malus coronaria*). This species of wild apple tree is found in North America, and at the time Michaux wrote his *Sylva Americana*, he says its nature had not been modified by cultivation. The wild apple tree of Europe, in a long series of years, has yielded a great number of species and varieties of fruit, in France alone, amount to nearly three hundred. Excepting those in the vicinity of Maine, the state of Vermont, and the upper part of New Hampshire, the crab apple is found, on both sides of the mountains, throughout the United States: but it appears to be most multiplied in the Middle States, and especially in the back parts of Pennsylvania and of Virginia. It abounds, above all, in the *Glades*, which is the name given to a tract 15 or 18 miles wide, on the summit of the Alleghany mountains, along the road from Philadelphia to Pittsburgh.

The ordinary height of the crab apple tree is 15 or 18 feet, with a diameter of 5 or 6 inches; but it is sometimes found 25 or 30 feet high, and 12 or 15 inches in diameter. The two stocks which I found by measurement to be of this size, stood in a field which had long been under cultivation, and this circumstance may have contributed to their extraordinary growth. They were insulated trees that in appearance exactly resembled the common apple tree. I have universally remarked that the crab apple grows most favourably in cool and moist places, and on fertile soils.

The leaves of this tree are oval, smooth on the upper surface, and, when fully developed, very distinctly toothed; some of them are imperfectly three-lobed. While young, they have a bitter and slightly aromatic taste, which leads to the belief that, with the addition of sugar, they would make an agreeable tea. Like the common apple tree, this species blooms very early in the spring. Its flowers are white, mingled with rose colour, and are collected in corymbs; they produce a beautiful effect, and diffuse a delicious odour, by which, in the glades where the tree is abundant, the air is perfumed to a great distance. The apples, which are suspended by short peduncles, are small, green, intensely acid, and very odoriferous. Some farmers make cider of them, which is said to be excellent; they make very fine sweet-meats also, by the addition of a large quantity of sugar.

No attempts have been made in the United States to improve the fruit of the crab apple tree, nor any experiments of uniting it, by grafting, with the species imported from Europe. These species succeed so perfectly, and furnish such excellent new varieties, that much time would be spent upon the crab apple, without bringing it to as high a state of improvement. Perhaps it might be cultivated with advantage for cider, but, aside from its utility in this way, it must be regarded only as a tree highly agreeable for the beauty of its flowers and for the sweetness of its perfume.

**CRAB-GRASS** (*Eleusine Indica*). Dog's-tail grass, Wire grass. The grass described under these several names in the *Flora Americana*, makes a fine carpeting in yards, lanes, and foot-paths, flowering in the Middle States in August. Cattle and hogs are very fond of it, and it is recommended as making excellent hay.

Another species of grass which in some places goes under the name of *Crab-grass*, is the *Digitaria sanguinalis*, or Finger-grass (see plate 7, f). This is a very troublesome annual in gardens and cultivated grounds, being very difficult to keep in subjection in the latter part of summer. (*Flor. Cestri*).

**CRACKS IN HEELS OF HORSES.** In farriery, little clefts which are said to be sometimes constitutional, but more frequently owing to the want of cleanliness and proper attention.

**CRADLE.** A frame consisting of long fingers arranged above a scythe, for the purpose of receiving the grain when harvesting. The scythe and cradle is comparatively a modern invention, the aid of which a hand can cut five or six times as much grain as could be harvested in the same time with a sickle.

**CRANBERRY** (*Vaccinium oxycoccus*). See Whortleberry.

The species of Cranberry most commonly found in the United States is the *Oxycoccus macrocarpus*. It is an indigenous, low trailing vine, growing wild in bogs and meadows, bearing a beautiful red berry of an exceedingly sour, though agreeable taste, much used in domestic economy for tarts and sweet-meats. The cranberry, says Mr. Kenrick, of Boston, is a plant of easy culture; and with but little expense, not a doubt exists that meadows which are now barren wastes, or yield nothing but coarse herbage, might be converted into profitable cranberry fields. According to Loudon, Sir Joseph Banks, who obtained this plant from America, raised, in 1831, on a square of 18 feet each way, 3½ Winchester bushels, which is at the rate of 400 bushels to the acre. Any meadow will answer. Captain Henry Hall, of Barnstable, has cultivated the cranberry 20 years. They grow well on sandy bogs after draining; if the bogs are covered with brush, it is removed, but it is not necessary to remove the rushes, as the strong roots of the cranberry soon overpower them. It would be well if, previous to planting, the land could be ploughed; but Capt. Hall usually spreads on beach sand, and digs holes four feet asunder each way, the same distance as for corn; the holes a foot, however, deeper. Into these holes, sods of cranberry roots are planted, and in the space of three years the whole ground is covered. The planting is usually performed in autumn. Mr. F. A. Hayden, of Lincoln, Mass., is stated to have gathered from his farm, in 1830, 400 bushels of cranberries, which brought him, in Boston market, $400.

An acre of cranberries in full bearing will produce over 200 bushels; and the fruit generally sells in the markets of Boston for $1.50 per bushel, and much higher than in former years. Although a moist soil is best suited to the plant, yet, with a suitable mixture of bog
CRANE'S BILL.

CRANE'S BILL (Geranium). A genus of plants comprising a large number of species, of which, according to Smith (Eng. Flor. vol. ii. p. 221), only thirteen are indigenous. The blue meadow crane's bill (G. pratense) is found in rich, rather moist pastures, and thickets, especially in the hilly parts of England. It is a perennial, flowering in June and July; flowers, of a fine blue, often irregularly striped or blotched with white, sometimes entirely white. The species of crane's bill called Herb Robert (G. Robertianum) possesses most medicinal virtues, and is found under hedges and in uncultivated places, flowering all through the summer. The stalks, and indeed the whole plant, is often quite red, as are the flowers, and the fruit is long and slender, resembling a crane's bill, after which it is named. The leaves are large, divided into many parts, and stand in pairs at every joint of their long-footed stalks. It is a very powerful astrigent, and may be given in any form, decocted fresh, or powdered when dry. Several indigenous species are found in the United States.

CRAP. A local name in some places for darning, and in others for buckwheat.

CRAPULA. See HOVEN.

CREAM. A thick, unctuous, yellowish coloured substance which collects on the surface of milk, when this is allowed to stand some time at rest. See BUTTER.

CREAM GAUGE, or GLASS. A graduated glass tube to ascertain the produce of cream. In a tube containing ten inches' depth of milk, every tenth of an inch will of course indicate one per cent. of cream. It may be used for many purposes, such as to ascertain the state of the animal's health, regular and quiet feeding, &c. (Quart. Journ. Agr. vol. ii. p. 245.)

CREAM-SLICE. A sort of wooden knife, twelve or fourteen inches in length.

CREOSOTE. A term derived from Greek words signifying "flesh preserver." It is the most important of the five new chemical products obtained from wood-tar, by Dr. Reichenbach. The other four, are Perillyl, Eupone, Picaonar, and Piticaoel, none of which have, as yet, been applied to any use in the arts. Creosote may be prepared either from tar or from crude pyrolignous acid. Its flesh-preserving quality is rendered of little use, from the difficulty of removing the rank flavour which it imparts.

CRESS. See AMERICAN CRESS.

CRESS, BITTER WINTER (Barbara vulgaris). See Winter Cress.

CRESS, INDIAN, or MAJOR NASTURTIUM (Tropaeolum majus), diminutiva of Tropaeum; a trophy; and T. minus). The major nasturtium being the most productive, as well of flowers and leaves as of fruit, is the one that is usually cultivated in the kitchen garden; the fruit being used in pickling, and the flowers and leaves in salads and for garnishing. They will flourish in almost any soil, but the one in which they are most productive, is a light fresh loam. In a strong rich soil, the plants are luxuriant, but they afford fewer berries, and those of inferior flavour. They like an open situation. Sow from the beginning of March to the middle of May; the earlier, however, the better. The seed may be inserted in a drill, two inches deep, along its bottom, in a single row, with a space of two or three inches between every two, or they may be dibbled in at a similar distance and depth. The minor is likewise often sown in patches. The major should be inserted beneath a vacant paling, wall, or hedge, to which its stems may be trained, or in an open compartment with sticks inserted on each side. The runners at first require a little attention to enable them to clumb, but they soon are capable of doing so unassisted. The minor either may trail along the ground, or be supported with short sticks. If water is not afforded during dry weather, they will not shoot so vigorously or be so productive. They flower from June until the close of October. The fruit for pickling must be gathered when of full size, and whilst green and fleshy, during August. For the production of seed, some plants should be left ungathered, as the first produced are not only the finest in

CRASS,
general, but are often the only ones that ripen. They should be gathered as they ripen, which they do from the close of August to the begin-
ing of October. They must on no account be stored until perfectly dry and hard. The finest and soundest seed of the previous year's production should alone be sown; if it is older, the plants are seldom vigorous. (G. W. John-
son, *Kitchen Gardens*).

**CRESS, WALL, or ROCK CRESS (Arabis).** A genus of plants of very different habit from the last, of which the species are numerous, and chiefly natives of the northern hemisphere. There are six species described by Smith (*Eng. Flor.* vol. iii. p. 209), but the wall cress (*Arab-
is thalaina*) is preferred. All the species have a pungent flavour. The plants are adapt-
ed for ornamenting rock work, and are propa-
gated from seeds or cuttings. The wild sorts are found frequent on old walls, stony banks or rocks, dry sandy ground, and cottage roofs.

**CRESS, WATER (Nasturtium).** There are several native species of water cress, which may be included in the following summary. Creeping yellow cress, annual yellow cress, amphibious yellow cress, or great water radish, and common water cress. They are branching herbs, almost invariably smooth, throwing out numerous radicles, and either altogether aqua-
tic, or at least growing in wet ground. (*Eng. Flor.* vol. iii. p. 191—5). Water cress (*N. officinale*) was seldom admitted as an object of cultivation, and then never to any extent, until Mr. Bradbury, of West Hyde, Herts, und-
took its cultivation for the London market. Mr. Bradbury considers that there are three varieties,—the green-leaved, which is easiest cultivated; small brown-leaved, which is the har
diest; and the large brown-leaved, which is the best, having most leaf in proportion to the stalk, and is the only one that can well be culti-
vated in deep waters. (*Trans. Hort. Soc. Lond.* vol. iv. p. 538.) The plants thrive best in a moderately swift stream, about an inch and a half deep, over a gravelly or chalky bottom, and the nearer its source the better: when there is choice, such situations, therefore, should be exclusively planted. If mud is the natural bottom, it should be removed, and gravel sub-
stituted. The plants are to be set in rows, which is most conducive to their health and good flavour, inasmuch as that they are regu-
larly exposed to the current of water, of which, if there is not a constant stream, they never

In shallow water, as above mentioned, the rows may be made only eighteen inches apart, but in deeper currents from five to seven feet are sometimes necessary. The beds must be cleared and re-planted twice a year, for in the mud and weeds which quickly collect, the plants not only will not grow freely, but it is difficult to separate them in gathering; it is likewise rendered imperative by the heads be-
coming small from frequent cutting. The tou-
its *Kitchen Gardens*).

**CRICKET.** The common or hearth cricket (*Gryllus*). This insect in England frequents kitchens and bakers' ovens, on account of the warmth of those places. An easy method of destroying them is to place phials half full of beer or any other liquid near their holes, and they will crawl into them, and can then be easily taken. A hedgehog soon clears a kitchen.

There are, as yet, no house-crickets in the United States, where the species inhabiting gardens and fields enter dwellings only by acci-
dent. The American crickets belong to a group of insects (*Gryllodes*) which naturalists have placed in the same class as the grasshop-
ers and locusts. They are distinguished by having wing-covers horizontal, and furnished with a narrow, deflexed outer border; antenna long and tapering; feet with not more than three joints, and two tapering downy bristles at the end of the body, between which, in most of the females, is a long spear-pointed piercing.

"There may be sometimes seen," says Dr. Harris, "in moist and soft ground, particularly around ponds, little ridges or hills of loose, fresh earth, smaller than those which are formed by moles. They cover little burrows, that usually terminate beneath a stone or clod of turf. These burrows are made and inhabited by mole-crickets, which are among the most extraordinary of the cricket kind. The com-
mon mole-cricket of this country is, when fully
grown, about one inch and a quarter in length, of a light bay or fawn colour, and covered with

364
CRICKET.

a very short and velvet-like down. The wing-covers are not half the length of the abdomen, and the wings are also short, their tips, when folded, extending only about one-eighth of an inch beyond the wing-covers. The fore-legs are admirably adapted for digging, being very short, broad, and strong; and the shanks, which are excessively broad, flat, and three-sided, have the lower side divided by deep notches into four finger-like projections, that give to this part very much the appearance and the power of the hand of a mole. From this similarity in structure, and from its burrowing habits, the insect deserves its scientific name of Gryllotalpa, derived from Gryllus, the ancient name of the cricket, and Talpa, a mole; and our common species has the additional name of brevipennis, or short-winged, to distinguish it from the European species, which has much longer wings. Mole-crickets avoid the light of day, and are active chiefly during the night. They live on the tender roots of plants, and in Europe, where they infest moist gardens and meadows, they often do great injury by burrowing under the turf, and cutting off the roots of the grass, and by undermining and destroying, in this way, sometimes whole beds of cabbages, beans, and flowers. In the West Indies, extensive ravages have been committed in the plantations of the sugar-cane by another species, Gryllotalpa didactyla, which has only two finger-like projections on the shin. The mole-crickets of Europe lays from two to three hundred eggs, and the young do not come to maturity till the third year; circumstances both contributing greatly to increase the ravages of these insects. It is observed that, in proportion as cultivation is extended, destructive insects multiply, and their depredations become more serious. We may, therefore, in process of time, find mole-crickets in this country quite as much a pest as they are in Europe, although their depredations have hitherto been limited to so small an extent as not to have attracted much notice. Should it hereafter become necessary to employ means for checking them, poisoning might be tried, such as placing, in the vicinity of their burrows, grated carrots or parsnips, the insect receiving the bait with such avidity as they might be said to swine, that swine will eat almost all kinds of insects, and that they are very sagacious in rooting them out of the ground. They might, therefore, be employed with advantage to destroy these and other noxious insects, if other means should fail.

"Cricket are, in great measure, nocturnal and solitary insects, concealing themselves by day, and coming from their retreats to seek their food and their mates by night. There are some species, however, which differ greatly from the others in their social habits. These are not unfrequently seen during the day-time in great numbers, in paths and by the road-side; but the other kinds rarely expose themselves to the light of day, and their music is heard only at night. With crickets, as with grass-hoppers, locusts, and harvest-flies, the males only are musical; for the females are not provided with the instruments from which the sounds emitted by these different insects are produced. In the male cricket these make a part of the wing-covers, the horizontal and overlapping portion of which, near the thorax is convex, and marked with large, oval spots, and irregularly curved veins. When the cricket shrills (we cannot say sings, for he has no vocal organs), he raises the wing-covers a little, and shuffle them together lengthwise, so that the projecting veins of one are made to grate against those of the other. The English name cricket, and the French cri-cris, are evidently derived from the cracking sounds of these insects. Mr. White, of Selborne, says that 'the shrilling of the field-cricket, though sharp and short, sometimes delights some hearers, filling their minds with a train of summer ideas of everything that is rural, verdant, and joyous;' sentiments in which few persons, if any, in America will participate; for with us the cracking of crickets does not begin till summer is gone, and the continued and monotonous sounds, which they keep up during the whole night, so long as autumn lasts, are both wearisome and sad. Where crickets abound, they do great injury to vegetation, eating the tender leaves of plants, and even devouring fruits and roots, whenever they can get them. Melons, squashes, and even potatoes are often eaten by them, and the quantity of grass that they destroy must be great, from the immense numbers of these insects which are sometimes seen in our meadows and fields. They may be poisoned in the same way as mole-crickets. Crickets are not entirely confined to a vegetable diet; they devour other insects whenever they meet with and can overpower them. They deposit their eggs, which are numerous, in the ground, making flaps for their reception with their long, spear-pointed piercers. The eggs are laid in the autumn, and do not appear to be hatched till the ensuing summer. The old insects, for the most part, die on the approach of cold weather; but a few survive the winter, by sheltering themselves under stones, or in holes secure from the access of water.

"The scientific name of the genus that includes the cricket is Acheta, and our common species is the Acheta abbreviata, so named from the shortness of its legs, which extend beyond the wing-covers. It is about three-quarters of an inch in length, of a black colour, with a brownish tinge at the base of the wing-covers, and a pale line on each side above the deflexed border. The pale line is most distinct in the female, and is oftentimes entirely wanting in the male.

"We have another species with very short or abortive wings; it is entirely of a black colour, and measures six-tenths of an inch in length from the head to the end of the body. It may be called Acheta nigra, the black cricket.

"A third species, differing from these two in being entirely destitute of wings, and in having the wing-covers proportionally much shorter, and the last joint of the feelers (palpi) almost twice the length of the preceding joint, is furthermore distinguished from them by its greatly inferior size, and its different colouring. It measures from three to above four-tenths of an inch in length, and varies in colour from dusky brown to rusty black, the wing-covers and hind-
most thighs being always somewhat lighter. In the brownish-coloured varieties, three longitudinal black lines are distinctly visible on the top of the head, and a black line on each side of the thorax, which is continued along the sides of the wing-covers to their tips. This black line on the wing-covers is never wanting, even in the darkest varieties. The hindmost thighs have on the outside three rows of short oblique black lines, presenting somewhat of a twilled appearance. This is one of the social species, which, associated together in great swarms, and feeding in common, frequent our meadows and roadsides, and, so far from avoiding the light of day, seem to be quite as fond of it as others are of darkness. It may be called _Acheta victate_, the striped cricket.

"These kinds of crickets live upon the ground, and among the grass and low herbage; but there is another kind which inhabits the stems and branches of shrubs and trees, concealing itself during the daytime among the leaves or in the flowers of these plants. The males begin to be heard about the middle of August, and do not leave us until after the middle of September. Their shrilling is exceedingly loud, and is produced by the tibia of other crickets, by the rubbing of one wing-cover against the other. These insects have been separated from the other crickets under the generic name of _Ocithus_, a word which means inhabiting flowers. They may be called climbing crickets, from their habit of mounting upon plants, and dwelling among the leaves and flowers. According to M. Salvi, the female makes several perforations in the tender stems of plants, and in each perforation thrusts two eggs quite to the pith. The eggs are hatched about midsummer, and the young immediately issue from their nests and conceal themselves among the thickest foliage of the plant. When arrived at maturity, the males begin their nocturnal serenade at the approach of twilight, and continue it, with little or no intermission, till the dawn of day. Should one of these little musicians get admission to the chamber, his incessant and loud shrilling will effectually banish sleep. Of three species which inhabit the United States, one only is found in Massachusetts. It is the _Ocithus virescens_, or white climbing cricket. The male is ivory-white, with the upper side of the first joint of the antenna, and the head between the eyes, of an ochre-yellow colour; there is a minute black dot on the under-sides of the first and second joints of the antenna; and, in some individuals, the extremities of the feet and the under-sides of the hindmost thighs are ochre-yellow. The body is about half an inch long, exclusive of the wing-covers. The female is usually rather longer, but the wing-covers are much narrower than those of the male, and there is a great diversity of colouring in this sex; the body being sometimes almost white, or pale greenish yellow, or dusky, and blackish beneath. There are three dusky stripes on the head and thorax, and the legs, antenna, and pincer are more or less dusky or blackish. The wing-covers and wings are yellowish white, sometimes with a tinge of green, and the wings are rather longer than the covers."

(Harris on Destructive Insects.)

**CROCUS.** A well-known bulbous plant, of which there are many varieties, all handsome. Plant in clumps; move them once in three years, to separate the offsets; they like a good light soil. Plant them two inches deep in the ground. Smith (Eng. Flor. vol. i. p. 46, and vol. iv. p. 262), describes four species of native English crocuses, viz., the saffron crocus, purple spring crocus, naked flowering crocus, and net-rooted crocus. See Saffron.

**CRONES.** A provincial word applied to the different descriptions of old ewes.

**CROOK.** A provincial term applied to a hook, as a yot-crook means a gate-hook.

**CROOM.** A provincial term applied to an implement with crooked or hooked prongs. There are muck-crooms, turnip-crooms, &c. It is sometimes written Crome.

**CROP.** The produce or quantity of grain, roots, or grass, &c. grown on a piece of land at one time; hence we have grain, root, and green crops. There is an able paper in the _Quart. Journ. of Agr._ vol. i. p. 56, by Mr. Henry Stephens, on the causes of destruction to crops, which may be consulted with advantage by the farmer. For course of crops, see Rotation of Crops.

**CROPPING.** An operation performed with a pair of shears, on the ears of horses, dogs, or other animals.

**CROSS-FURROW.** The grip or furrow which receives the superfluous rain-water from the outer furrows, and conveys it from the land into a ditch or other outlet. The operation of making these cross-furrows is sometimes performed by the spade, and at others by the plough.

**CROTCH.** A country term for a hook.

**CROW, THE CARRION (Crows corone).** The carrion crow, like the raven which it so much resembles, is a denizen of nearly every part of the world. Crows are even found in New Holland and the Phillipine islands of the Pacific Ocean. They are comparatively rare in northern latitudes, where the raven most abounds. The crow is exceedingly mischievous in his depredations about farms and dwellings, where he sucks eggs, carries off chickens and other young birds. But the most serious mischief of which the crow is guilty in the United States, is that of pillaging the fields of Indian corn. He commences at the planting time, by rooting out the grain as soon as the sprout shows above the ground, and in autumn, when the crop ripens, flocks, sometimes sufficient to blacken the fields, do extensive damage.

"The crow," says Nuttall, "like many other birds, becomes injurious and formidable only in the gregarious season, at other times they live so scattered, and are so shy and cautious, that they are but seldom seen. But their armies, like all other and terrific assemblies, have the power, in limited districts, of doing very sensible mischief to the agricultural interests of the community; and, in consequence, the poor crow, notwithstanding his obvious services in the destruction of vast hosts of insects and their larve, is proscribed as a felon in all
civilized countries, and, with the wolves, panthers, and foxes, a price is put upon his head. In consequence, various means of en-snaring the outlaw have been had recourse to. Of the gun he is extremely cautious, and suspects its appearance at the first glance, perceiving with ready sagacity the wily manner of theowler. So fearful and suspicious are they of human artifices, that a mere line stretched round a field is often found sufficient to deter these wild birds from a visit to the corn-field. Against poison he is not so guarded, and sometimes corn steeped in hellebore is given him, which creates giddiness and death. According to Buffon, pieces of paper in the form of a hollow cone, smeared inside with bird-lime, and containing bits of raw meat, have been employed. In attempting to gain the bait, the dupe becomes instantly hood-winked, and, as the safest course out of the way of danger, the crow flies directly upwards to a great height, but becoming fatigued with the exertion, he generally descends pretty near to the place from which he started, and is then easily taken.

"Another curious method, related by the same author, is that of pinning a live crow to the ground by the wings, stretched out on his back, and retained in this posture by two sharp, forked sticks. In this situation, his loud cries attract other crows, who come swooping down to the prostrate prisoner, and are grappled in his claws. In this way each successive prisoner may be made the innocent means of capturing his companion. The reeds in which they roost, when dry enough, are sometimes set on fire also, to procure their destruction; and, to add to the fatality produced by the flames, gunners are also stationed round to destroy those that attempt to escape by flight. In severe winters they suffer occasionally from famine and cold, and fall sometimes dead in the fields. According to Wilson, in one of these severe seasons, more than six hundred crows were shot on the carcase of a dead horse, which was placed at a proper shooting distance from a stable. The premiums obtained for these, and the price procured for the quills, produced to the farmer nearly the value of the horse when living, besides affording feathers sufficient to fill a bed!

"The crow is easily raised and domesticated, and soon learns to distinguish the different members of the family with which he is associated. He screams at the approach of a stranger; learns to open the door by alighting on the latch; attends regularly at meal times; is very noisy and loquacious; imitates the sound of various words which he hears; is very taken, given to hiding curiosities in holes and crevices, and is very fond of carrying off pieces of metal, corn, bread, and food of all kinds; he is also particularly attached to the society of his master, and recollects him sometimes after a long absence.

"It is commonly believed and asserted in some parts of this country, that the crows engage at times in general combat; but it has never been ascertained whether this hostility arises from civil discord, or the opposition of two different species, contesting for some exclusive privilege of subsisting-ground. It is well known that rooks often contend with each other, and drive away, by every persecuting means, individuals who arrive among them from any other rookery.

"The crow is much smaller than the raven, and is of a deep black with violet reflections. The bill and feet are also black. The iris hazel. (The European bird is twenty inches, or nearly, and has the feathers of the neck narrow and distinct.)"

Soaking seed-corn for 24 or 48 hours in a strong solution of chamber's salts, is said to effectually prevent crows, black-birds, and squirrels from pulling up the grain.

Wilson was the first ornithologist who discovered an American species differing from the common crow, and which he called the fish crow (*corvus ossifragus*). It is met with along the coast of the Southern States and as high up as New Jersey. It keeps apart from the common species, from which, however, it differs but slightly in appearance, being about 16 inches in length whilst the common crow measures about 18 inches. Instead of assembling to roost among the reeds at night, it retires, toward evening, from the shores which afford it a subsistence, and perches in the neighbouring woods. Its notes, probably various, are at times hoarse and guttural, at others weaker and higher. They pass most part of their time near rivers, hovering over the stream to catch up dead and perhaps living fish, or other animal matters which float within their reach; at these they dive with considerable celerity, and seizing them in their claws, convey them to an adjoining tree, and devour the fruits of their predatory industry at leisure. They also snatch up water lizards in the same manner, and feed upon small crabs; at times they are seen even contending with the gulls for their prey. It is amusing to see with what steady watchfulness they hover over the water in search of their precarious food, having, in fact, all the traits of the gull; but they subsist more on accidental supplies than by any regular system of fishing. On land they have sometimes all the familiarity of the magpie, hopping upon the backs of cattle, in whose company they, no doubt, occasionally meet with a supply of insects when other sources fail. They are also regular in their attendance on the fishermen in New Jersey, for the purpose of gleaning up the refuse of the fish. They are less shy and suspicious than the common crow, and, showing no inclination for plundering the corn-fields, are rather friends than enemies to the farmer. They appear near Philadelphia, from the middle of March to the beginning of June, during the season of the shad and herring fishery.

They breed in New Jersey in tall trees, having nests and eggs very similar to those of the preceding species, and rear a brood of four or five young, with whom they are seen in company in the month of July.

This species bears some resemblance to the rook in general appearance, and by the bare space near the bill, but it is smaller, longer tailed, and wholly different in its habits and mode of living.

*The Hooded Crow (Corvus cornix) resembles* 367
the carrion crow in appearance; but is only a constant resident of the northern parts of England and the western islands of Scotland; it is more destructive to the farmers’ lambs, &c. than the carrion crow. Its colour is black. Length, twenty inches. (Yarrell’s Brit. Birds, vol. ii. p. 79—83.)

CROW-FOOT, or Crane’s Bill. The species usually known by this name in England, is the Ranunculus acris or botanists. This, with all its varieties, is a common plant. The common medicinal crow-foot is the medicinal plant, which, however, is only used externally, the application of the recent leaves or root producing a blister. The most poisonous variety is that called spear-wood. The plant known in the United States by the name of crow-foot, or spotted crane’s-bill, is the spotted geranium (Geranium maculatum), a perennial tuberous root, found along fence-rows, in meadows, woodlands, &c., flowering in May and June. The root is astringent and has been found useful in diarrhoea, homorrhages, &c. See Flora Cestrica.

CROW NET. A net made of double thread or fine packthread, principally used for catching wildfowl in the winter season; but which may also be employed on newly sown cornfields for catching pigeons, crows, and other birds; and, even in stubble-fields, if the stubble conceals the nest from the birds.

CROWN IMPERIAL (Fritillaria imperialis). Native of Persia, with a large, scaly, bulbous, or orange-coloured, disagreeably smelling root. Blows pendent red flowers in April and May. There are three varieties, the red-flowered, the red-striped-flowered with striped leaves, and the yellow-striped; that blowing a yellow flower is the handsomest. Propagate by offsets every third year, taking up the bulbs in July for that purpose. It loves a sandy loam, and is averse to manure or wet.

See Fritillaria.

CRUCIFORM-PLANTS (Cruciferae), a class comprehending such garden vegetables as the cabbage, cauliflower, broccoli, sea-kale, turnip, radish, mustard, and in fact almost every culinary article, except spinach. The class derives its name from the flowers having four petals or flower-leaves, disposed in the form of a cross, as exemplified in the wall-flower. It is remarked by botanists, that not a single species included in this group is poisonous. Even that great pest among weeds, charlock, or wild radish, which belongs to the cruciform class, affords rich young most excellent and wholesome greens.

CRUPPER. A term applied to the rump of a horse; also to a roll of leather put under a horse’s tail, and drawn up by a strap to the buckle behind the saddle.

CRUSHERS FOR GRAIN, are evidently coming fast into use; the saving of food, by giving the grain in a broken state, being certainly very considerable. It is a practice at least as old as the days of Samuel Hartlib, who mentions it with approbation in his “Legacie.” Machines for cracking and crushing Indian corn by hand for feed, are quite common in the United States.

CUCKOO SPIT. Applied to a kind of frothy substance frequently found on plants, containing insects. See Froghoppers.

CUCUMBER (Cucumis sativus. From κοκυμ'ς or κοκυμές. Varro says, “Cucumeres dicuntur a curvore, ut curvimere dicti”). The following are the chief varieties:—1. Early short green prickly; 2. early long green prickly; 3. most long green prickly; 4. early green cluster; 5. white Dutch prickly; 6. long smooth green Turkey; 7. large Japanese green; 8. Flanagan’s; 9. Russian; 10. white Turkey; 11. Nepal; 12. fluted (from China); 13. the snake.

The early short prickly is about four inches long, and is often preferred for the first crop, as being a very plentiful bearer, quick in coming into production, and the hardest of all the varieties. The early long prickly is about seven inches long; it is a hardy, abundantly bearing variety, but not quick in coming into production. It is generally grown for main crops. The longest prickly is about nine or ten inches in length; it is a hardy, good bearer. There is a white sub-variety. The early green cluster is a very early bearer. Its fruit is about six inches long. It is chiefly characterized by its fruit growing in clusters. The whole plant grows compact, and is well suited for hand-glass crops. The white Dutch prickly is about six inches long; it has an agreeable flavour, though differing from most of the others. It comes quickly into bearing.

The other varieties are slow in coming into production, and are chiefly remarkable for their great size. The Nepals often weighs twelve pounds, being occasionally eight inches in diameter and seventeen in length. It is a native of Calcutta. The snake cucumber is very small in diameter, but attains the length, it is said, of several feet.

A fresh loam, rather inclining to lightness than tenacity, as the top-spit of a pasture, is perhaps as fine a soil as can be employed for the cucumber. It will succeed in any open soil of the garden for the hand-glass and natural ground crops.

The out-door culture of cucumbers practised throughout the United States is so familiarly known as to require no particular description. In the neighbourhood of large cities the large demand for cucumbers causes these to be included among the articles of field-culture, and this is done to great profit by the Long Island and New Jersey truck farmers, for the supply of the New York and Philadelphia markets. It is a great object to get the produce into market as early as possible, as only a few days advantage makes a great difference in the value of this, in common with most other articles supplied by gardeners, fruiters, and truckmen. Thomas G. Bergen, an intelligent and experienced gardener on Long Island, communicated to the editor of the Cultivator the following account of his method of raising cucumbers, together with his estimate of the produce and profits of the crop.

“Cucumbers will grow on any good soil, but to have them early we require a rich sandy one, of a dark colour; yellow and light-coloured ones being later. The field, if possible, re-
CUCUMBER.

quires to be protected from the north-west winds, and be situated near the bay or river, where there is always less danger from late frosts. The south winds, with us, in May and June, retard vegetation more than any other, in consequence of their being chilly and cool, which qualities they receive from the ocean.

Ground intended for cucumbers we prefer ploughing in the beginning of September in the ten days following the first day of the month, and sowing with rye; the pasture which this produces pays for the labour, and among its advantages are, the prevention of weeds going to seed and troubling us in the spring; the soil not blowing about in winter, especially on the knolls; neither is it so liable to blow when ploughed in the spring, in consequence of the roots of the plants, and the sustenance afforded to the crop by the decay of the rye. Previous to ploughing for the crop, there should be spread about seven or eight horse loads of street or horse manure to the acre; but if the soil is poor, more will be necessary, and the ploughing should take place immediately after the spreading. The ground is then harrowed over two or three times until it is mellow, furrowed shallow, with a plough, into hills four and a half feet asunder, manured with half a shovelful of a hill, which is flattened down with a hoe and covered about an inch thick with fine soil. Short horse manure, carted out of the pen the preceding fall, and cut over early in the spring once or twice, and made fine, is preferred for the hills; but this not being generally sufficiently abundant, we procure the manure of cows which have been fed on distillers' slops, mixed with that of horses, so as to make it sufficiently firm to handle with a fork, from New York in the fall, which we mix with the hog manure. The manure should be cool, for fermentation in the hills is injurious to the plants.

The sooner the seed is planted after ploughing the better; the time of planting depends upon the forwardness of the season, and it is generally commenced when single apricot blossoms are open, but some seasons earlier. About a week is occupied in putting in the first seed, and nearly the same period in planting over the first and second times. The casualties to which the seeds and plants are subject induces us to continue putting in seed almost every day for this space of time, so as to make certain work. It sometimes happens, when the weather has been unfavourable, that every hill in some fields is planted over the third, and even the single hills the fourth time. I prefer spreading the first seed in the south half of the hills, the first planting over in the northwest, and the second in the northeast quarters; if it becomes necessary to plant over the third time, I put the seed in the south half, where the first seed by that time is rotten. If this plan is properly followed, the different plantings will not interfere with each other. We generally put in from thirty to forty seeds each time, and cover them with fine soil from three-quarters to an inch deep. Sprouting the seed previously to planting does not succeed well early in the season, but does sometimes when the weather is favourable in the latter part. Cucumber seed is the tenderest of the vine kind, for if, after planting at the usual depth, wet weather should follow, it is almost certain to rot; if dry, it dries out; if, when favourable to their vegetating, and the plants have advanced so as to be breaking ground, a storm should occur, they generally perish; a northeaster of three or four days' continuance destroys the plants when young, and some instances when more than a week old; if up too early, a late frost is apt to sweep them clean. Seed to vegetate requires to be near the surface of the wet soil, not buried deep into it; our ignorance of the weather which will follow after planting, causes most of our errors; when planted in a heavy soil, it is less liable to rot and dry out than in a sandy one, but the fruit is later. If it happens that there are more plants in a hill than we require, we find it an easy matter to eradicate them with the hoe and fingers, but it is not so easy to place them in the hills when deficient.

When the first rough leaves of the plants are about the size of a twenty-five cent piece, a cultivator is run through the rows both ways, and they receive the first hoeing; the plants are also thinned out, so as not to crowd each other. In hoeing, the soil between the plants should not be disturbed; large weeds (if any) must be pulled out; and fine soil drawn around the plants up to the seed leaves, so as to cover small weeds. The hill must be made flat and not concave.

We are careful not to hoe while the plants are very young, for if a storm should occur shortly after the operation has been performed, the hills soak in too much water, which is injurious. Ten or twelve days after the first hoeing, the plants (if good) are thinned to six or eight in a hill, leaving the largest ones, and if possible three or four inches apart. About eighteen days after the first hoeing, or about the time when single blossoms open, we run a one-horse plough twice through a row each way (if the ground is hard, three times), throwing the furrow from the hills, and then commence the second hoeing, which is performed in the same manner as the first, care being taken not to earth up higher than the seed leaves, and to scrape out the crust between the plants, if the ground is hard or covered with weeds; they are also, if the plants are fair, thinned down to five in a hill. "When the vines extend so that single ones meet each other between the hills, to prevent injury they are carefully laid aside by hand, or with a short stick, and the cultivator for the last time is run once through a row each way. They then receive the third and last hoeing, the ground being loosened and drawn up around the hills with the hoe, and broken between the plants with the fingers. It is customary to leave five plants in a hill, standing from four to five inches apart, but some reduce them to four; have tried no experiment to test which is the best.

Cucumber vines will yield fruit about eight weeks, and the fields are picked over at least every second and sometimes every day. In picking, a light stick with a cross-piece framed to it so as to resemble the letter T, is made use of to push the leaves aside and more readily to discover the fruit.

369
We are acquainted with the system of rotation of crops, and it has been practised among our farmers for years, but cucumbers, as well as some other vegetables, do not seem to require it. I have a piece of about half an acre on which I have cultivated them for the last ten successive years, ploughing in the usual quantity of manure every second year, and they have flourished as well as on the adjoining ground, which has been similarly manured, and on which the crops have been changed.

"The following is the quantity planted, produced, and amount of sales, for the last four years, viz."

"During each of these years large quantities of cullings, and, when unseasonable, good ones, were sold to the hogs and cattle, of which no account was kept." (Cultivator, v.)

CUCUMBER, insects attacking.

In the United States the vine of the cucumber is preyed upon at all ages, but more especially when very young and tender, by various insects, which make it necessary to replant frequently, and very often entirely destroy the hopes of the gardener and truckman. Among the most destructive of these is the beetle generally known by the names of striped bug, cucumber bug, and striped Galeruca. It is of a light yellow colour above, with a black head, and a broad black stripe on each wing-cover. Its length is rather more than one-fifth of an inch. It belongs to the extensive tribe of leaf-eating beetles, called by naturalists Chrysomelians, a word applied to designate golden beetles, many of which are of the most brilliant colours, with the finest metallic lustres.

Dr. Harris informs us that the striped cucumber bug in early spring destroys the tender leaves of cucumbers, squash, and melon vines are out of the ground. As soon, however, as the leaves of these come up and begin to expand, they are attacked by the bug; and, as several broods are produced in the course of the summer, it may be found at various times on these plants, till the latter are destroyed by frost. Great numbers of these little beetles may be obtained in the autumn from the flowers of squash and pumpkin vines, the pollen and germs of which they are very fond of. They get into the blossoms as soon as the latter are opened, and are often caught there by the twisting and closing of the top of the flower, and when they want to make their escape, they are obliged to gnaw a hole through the side of their temporary prison. The females lay their eggs in the ground, and the larvae probably feed on the roots of plants, but they have hitherto escaped my researches.

Various means have been suggested and tried to prevent the ravages of these striped cucumber beetles, which have become notorious throughout the country for their attacks upon the leaves of the cucumber and squash.

Dr. B. S. Barton, of Philadelphia, recommended sprinkling the vines with a mixture of tobacco and red pepper, which he stated to be attended with great benefit. Watering the vines with a solution of one ounce of Glauber's salts in a quart of water, or with tobacco water, an infusion of elder, of walnut leaves, or of hops, has been highly recommended. Mr. Gourgas, of Weston, has found no application so useful as ground plaster of Paris; and a writer in the 'American Farmer' extols the use of charcoal dust. Dr. Scudder recommended sifting powdered hot ashes upon the plants when they are wet with the morning dew, and others have advised sulphur and Scotch snuff to be applied in the same way. As these insects fly by night as well as by day, and are attracted by lights, lighted splinters of pine knots or of staves of tar barrels, stuck into the ground during the night around the plants, have been found useful in destroying these beetles. The most effectual preservative both against these insects and the equally destructive black flea-beetles which infest the vines in the spring, consists in covering the young vines with millinest stretched over small wooden frames. Mr. Levi Bartlett, of Warner, N. H., has described a method for making these frames expeditiously and economically, and his directions may be found in the second volume of the New England Farmer, p. 305, and in Fessenden's New American Gardener, sixth edition, p. 91." (Harris.)

A correspondent of the Cultivator says that a thin layer of tow doubtless suggested the millinet frame protection just referred to.

Mr. Bergen, whose mode of cultivating cucumbers has been given, makes the following observations in relation to the insect enemies of the plant:—

"The insects which trouble and destroy the plants are the black worm and striped bugs; the first is apt to be numerous in ground which was occupied the preceding year with red clover; they cut off the plants at or above the surface in the night, and are generally hunted out early in the morning, when their burrowing is fresh and they lie near the surface, until the ground is cleared of them; the striped bug or yellow fly eats the plants in the day time, and is sometimes very destructive on land where a crust is formed on the surface, which, being raised up by the young plants, affords them a harbour. The best remedy is, with the fingers to catch and destroy them in the morning when the dew is on them and they are chilled, which prevents their flying and escaping as freely as when the sun has warmed them. Sandy land, having no crust to shelter these pests, is generally exempt from their depredations."

The cucumber flea-beetle referred to, is a little, black, jumping insect, well known from the injury done by it in the spring, not only to the young plants of the cucumber, but to those of the cabbage, turnip, rutsa baga, mustard,
radish, cress, potato, and some others of the cruciferous family. It is closely allied to the turnip-fly or more properly the turnip flea-beetle, which lays waste the turnip fields in Europe, devouring the seed-leaves of the plants as soon as they appear above ground, and continuing their ravages upon new crops throughout the summer. It is stated in Young's *Annals of Agriculture* (enlarged, viii.) that there is an injury to the radish, horse-radish, various kinds of cresses, and on the mustard, and turnip, early in May, and indeed at other times throughout the summer. It is very injurious to young plants, destroying their seed-leaves as soon as the latter expand. Should it multiply to any extent, it may, in time, become as great a pest as the European turnip-fly, which it closely resembles in its appearance, and in all its habits. Though rather larger than the cucumber flea-beetle, and of a longer oval shape, it is considerably less than one-tenth of an inch in length. It is of a polished black colour, with a broad wavy buff-coloured stripe on each wing-cover, and the knees and feet are reddish-yellow. Specimens are sometimes found having two buff-yellow spots on each wing-cover instead of the wavy stripes.

"In England, where the ravages of the turnip flea-beetle have attracted great attention, and have caused many and various experiments to be tried with a view of checking them, it is thought that 'the careful and systematic use of lime will obviate, in a great degree, the danger which has been experienced,' from this insect. From this and other statements in favour of the use of lime, there is good reason to hope that it will effectually protect plants from the various kinds of flea-beetles, if dusted over them, when wet with dew, in proper season. Watering plants with alkaline solutions, it is said, will kill the insects without injuring the plants. The solution may be made by dissolving one pound of hard soap in twelve gallons of the soap Suds left after washing. This mixture should be applied twice a day with a water pot. Kölliker highly recommends watering or wetting the leaves of plants with an infusion or tea of wormwood, which prevents the flea-beetles from touching them. Perhaps a decoction of walnut leaves might be equally serviceable. Great numbers of the beetles may be caught by the skilful use of a deep bag-net of muslin, which should be swept over the plants infested by the beetles, after which it is removed without injuring the plants. This net cannot be used with safety to catch the insects on very young plants, on account of the risk of bruising or breaking their tender leaves." (Harris.)

Dr. Harris says, that several years ago he observed cucumber vines much infested by some minute jumping insects, rather less than one-sixteenth of an inch long, of a broad oval shape, and black colour, without wing-covers or wings, but furnished with short, thick hinder thighs. They injured the vines very much by eating holes into or puncturing the leaves, and were expelled by dusting the plants with flower of sulphur. These cucumber-skippers were so soft and tender, and withal so agile, that it was difficult to catch without crushing them. Consequently he was unable to examine them thoroughly, and failed to preserve specimens of them.

Since the time referred to they have escaped the doctor's observation. He, however, thinks they were very different from the little flea beetles just described as belonging to the *Haltica* family.

**CUCUMBER TREE.** There are three spe-
cies of the magnolia, natives of the United States, which go under this name, from the resemblance of their cones to the green fruit of the cucumber. One of these, the *Magnolia acuminata*, is a tree of considerable size, sometimes exceeding eighty feet in height and three or four feet in diameter. The trunk is perfectly straight, of a uniform size, and often destitute of branches for two-thirds of its length. The tree is one of the most splendid ornaments of the American forests. The leaves are six or seven inches long and three or four broad, upon old trees, and often twice the size upon saplings. Their form is oval, entire, and very sharp pointed, from which last characteristic the tree derives its specific name of *acuminata*. They fall off in autumn. The flowers are five or six inches in diameter, bluish, and sometimes white with a tint of yellow. They have a feeble odor, and being large and numerous, give a fine effect in the midst of the elegant foliage. It makes a superb ornamental tree in lawns, &c.

The cones or fruit are about three inches long, and one inch in diameter, nearly cylindric in shape, and often a little longer at the extremity than at the base. When green, they very much resemble a young cucumber. They have cells, each of which contains one rose-coloured seed, which, before it escapes, remains suspended on the outside by a filament, like those of the great and small magnolias. Most of the inhabitants of the country bordering on the Alleghanies gather the cones about midsummer, when half ripe, and steep them in whisky: a glass or two of this liquor, which is extremely bitter, they habitually take in the morning, under the alleged excuse of preserving them against autumnal fevers.

The most northern point at which Michaux observed the cucumber tree, was on the Niagara river, in the latitude of 43°. It abounds along the whole mountainous tract of the Alleghanies, to their termination in Georgia, a distance of 900 miles. It is, however, rarely met with at a greater distance than 40 or 50 miles from the mountains, either eastward or westward. Michaux concludes that it is a stranger to all the Atlantic parts of the United States, to the distance of 100, 150, and 200 miles from the sea, the nature of the soil and extreme heat of the climate being utterly uncongenial to its growth. It may, however, be found in a highly flourishing condition at the seats of the Messieurs Dupont, on the banks of the streams in the back of Doubtless town, anywhere in the vicinity of Philadelphia, especially on the banks of the Schuylkill, and perhaps still further north.

Another species of magnolia, which, in its general appearance and in the form of its fruit, very nearly resembles the preceding, has been confounded with it by the inhabitants of the regions in which it grows. Michaux calls it the heart-leaved cucumber tree (*Magnolia cordata*). He found it on the banks of the Savannah river in Upper Georgia, and also on the streams in the back of Doubtless town, of South Carolina, approaching within twelve miles of Augusta. It grows to the height of forty or fifty feet, with a diameter of twelve or fifteen inches.

The bark is rough and deeply furrowed like that of the sweet gum and young white oak. The flowers, which appear in April, are yellow, and nearly four inches in diameter. The succeeding cones are about three inches long and one inch thick, and with the seeds, resemble those of other magnolias. The beauty of its yellow flowers form an agreeable contrast with its luxuriant foliage, and, together with its capacity to resist intense cold, recommend it highly as an ornamental tree in northern situations.

The long-leaved cucumber tree, (*Magnolia auriculata*) is also remarkable for the beauty of its foliage and for the size of its flowers, which possess an agreeable odor. Michaux states that it appears form his observations to be confined to that tract of the Alleghany Mountains which traverse the Southern States, at the distance of nearly 300 miles from the sea. Besides the popular name already given, it is also called Indian physic.

The growth of this is far below that of the first named tree, nor does it even attain the size of the heart-leaved species. Its limbs are widely spread and sparingly branched, which, when the tree is stripped of its leaves, give it a peculiar effect. The leaves are eight or nine inches long, and much larger on the youngest trees. They are broader at the top than towards the bottom, or base, which is divided into rounded lobes, resembling the ears of some animals, whence a common name, *auriculata*. The flowers are three or four inches in diameter, of a fine, white colour, of an agreeable odour, and situated at the extremity of the young shoots, which are of a purplish-red, dotted with white. The cones are oval, three or four inches long, and, like those of the umbrella tree, another species of magnolia, of a beautiful rose colour when ripe. Each cell contains one or two red seeds. The bark has an agreeable aromatic odour, and is infused in spirits as a popular remedy in rheumatic affections. Inasmuch as the virtues ascribed to this spirituous preparation are very doubtful, and the practice of using it fraught with great danger, not only from misapplication at improper stages of disease, but from its tendency to form a vicious taste for ardent drinks, it had best be dispensed with, and other better and less mischievous remedies resorted to. The tree flourishes in Europe, where it is a popular ornamental tree. (Michaux.)

CUD. In cattle, the food in the first stomach, is to be chewed over again and passed into the second to be digested. See CHEWING THE CUD.

CUDWEED, or EVERLASTING. A shrub or herbaceous plant belonging to a genus (*Gnaphalium*) containing one hundred and twenty species, most of which are indigenous to the Cape of Good Hope. There are a few species in Europe, India, and in South as well as North America. The generic name is derived from a Greek word signifying soft down, or wool, with which the plants are clothed. The species known in this country is the *Purple Gnaphalium*, a biennial growing in dry, open woodlands, &c., to the height of six, twelve, or fifteen inches, producing dingy pur-
CULLEY.

Plish flowers in July and August. The Miry, or Marsh Gnaphalium, or Marsh Cudweed, with an annual root, and stem four to six or eight inches high, bearing flowers in dense clusters, of a yellowish-tawny; growing in low grounds, dried-up ponds, &c., Genus Gnaphalium, or Common Cudweed, an annual root, producing a stem six to nine inches high; growing on dry hills, old fields, &c., bearing flowers of a pale tawny, or straw-colour. Many-headed Gnaphalium, called Life Everlasting, with an annual root, and stem one to two feet high, growing in old fields and pastures, flowering in August and September, the blossoms being slender and of a yellowish colour. An infusion of this plant has enjoyed much reputation, as a popular remedy for dysentery. Pearly Gnaphalium (G.marginatum), a very handsome species, with a perennial root, stem one to two feet high, and beautiful white flowers. Dicicous Gnaphalium, commonly called Mouse-cow Cudweed, with a perennial root, stem two or three to six inches high. The White Plantain, or Plantain-head Cudweed, is a variety of this last species. (See Flor. Cestric.)

CULLEY. The name of a distinguished family of farmers. The agriculture of England is under very considerable obligations. Two brothers of the family, Matthew and George Culley, were seated originally on their paternal property of Denton, at Gainsford, near Darlington (now, 1841, in the possession of Mr. Matthew Culley), whence they migrated in June, 1767, to Fenton, in Glendale, county of Northumberland; and "on the 4th of August in that year, on my road to a fair at Kelso," says Mr. George Culley, in a letter to Arthur Young (Journ. of Agr. vol. xx. p. 162), "I first saw a field of drilled turnips." "They carried with them into Glendale," says Mr. John Grey (Journ. of Roy. Agr. Soc. vol. ii. p. 152), "superior knowledge and intelligence, which they at once brought to bear in their extensive undertakings with unremitting application and perseverance. That they were successful in their efforts is an undoubted fact. Thus on the farm of Wark, near Coldstream, which they entered in May, 1786, the crop was valued to them from the preceding tenant, and was estimated at 15 bushels per acre for oats, and 9 for wheat. But the crop on the same farm, after being in their occupation for fifteen years, was estimated at 84 bushels per acre for oats, 62 for wheat, and 72 for barley. (Ibid. p. 158.) The rent of this farm of 1200 acres in 1786 was 800l.; in 1812 it was 3200l. Matthew Culley died in 1805, in the 73rd year of his age, and George in 1814, aged 79, both in Glendale. The Culleys were the warm friends and correspondents of the celebrated Bakewell, of Dishley, from whose flock they introduced the breed of Leicester sheep, which is still a prevailing kind in Northumberland; and this breed is still preserved in a state of purity by the present owner of Denton, Mr. Matthew Culley, to whom I am indebted for several of the facts of this memoir. The attention which they paid to the improvement of their breed of live-stock was unremitting, and with a success which was equal to their labours. They had the public spirit, too, not to conceal the improvements which they effected: they published one or two valuable works, and were not unfrequently contributors to the agricultural periodicals of the day. Thus in the Journ. of Agr. vol. xiv. p. 180, there is a letter from Mr. George Culley in praise of the Dishley breed of sheep; and at p. 470, on the wool, sheep, and corn of Northumberland; again on sheep, in vol. xvii. p. 347, and vol. xix. p. 147; on turnips, vol. xx. p. 167. In 1786, George Culley published a useful practical little book (Observations on Live Stock), which was reprinted in 1793. Arthur Young describes its author (Journ. of Agr. vol. xxiii. p. 519), as "a man of the most extensive practice, and the deepest knowledge of his art." He also published, in conjunction with Mr. Bailey, the agricultural reports of Northumberland, Cumberland, and Westmoreland, 1797—1805.

CULM. Among botanists, signifies straw or hault; defined by Linnaeus to be the proper stem of grasses, scitamineous plants, and the like, which elevates the leaves, flower, and fruit. This sort of stem is tubular or hollow, and has frequently knots or joints, distributed at certain distances through its whole length. CULMIFEROUS PLANTS. Such as produce culms, or have a smooth jointed stalk, and their seeds enveloped in chaffy husks, grass-like.

Culmiferous crops include wheat, barley, oats, rye, Indian corn, tobacco, cotton, &c., all of which have stems mostly jointed. They are all regarded as robbers and exhausters of the soil, some in a far greater degree than others. If cut green, or when in blossom, they are far less than when allowed to mature their seeds.

CULTIVATOR. A name given to implements of the horse-hoe kind, invented for stirring the earth. The implements called cultivators are very extensively used in the United States, being found particularly serviceable in running between the rows of Indian corn, sugar beets, and other root crops planted in drills or rows. They stir up and loosen the earth, and at the same time keep it free from weeds and grass. Their operation is somewhat between those of the plough and the harrow, and as they do not penetrate very deep, they leave below the surface and vegetable matter of the sod turned under by the plough, and at the same time do no injury to the roots of the plants under culture, unless these are too far advanced in their growth. The cultivator should generally be run through a crop twice at a dressing, and if the soil be stiff or grassy, it may be passed oftener or renewed at short intervals. The implements most preferred in the United States bear a strong resemblance to the horse-hoes of Europe. They are made with teeth of different forms, best adapted to the various purposes, of skimming the surface and destroying weeds, or for doing this and also breaking up and pulverizing the earth. The best kind of cultivators are those which are constructed so as to admit of being made wide or narrow, according to the width of the rows. They perform so much of the labour for which the hoe and the plough were once resorted to, as to have greatly lessened the expenses of tillage in the
Indian corn crop, to say nothing of their great importance in the culture of root crops. Among implements of this kind in high repute in the United States, is Bement’s Improved Cultivator and Horse-hoe, which not only admits of being widened and contracted at pleasure, but is so constructed as to be easily adapted to soils of different textures, being furnished with teeth or shares of various forms, suited to the nature of the soil to be operated on. An excellent cultivator, not protected by patent, is in general use among the Pennsylvania farmers near Philadelphia, where it can be procured at the agricultural implement stores for about $2. See Graham and Scarifier.

CUMIN SEED. The seed or fruit of the Cuminum cyminum, which is imported from Sicily and Malta. It has been occasionally grown in England, but as it does not produce its seeds until the second year, and requires a rich, and consequently high-rented soil, the doctor has been induced to cultivate it. (Bot. Hist. vol. ii. p. 323.) Cumin is a plant of little beauty, and in a garden merely requires to be sown in any open border to succeed. CURULIO (Curculionidae). A name applied by naturalists to designate a family of beetles, distinguished from other insects of the same tribe by their shortness and thickness, and from each other by the length and direction of their snouts. The corn-weevil, so destructive to grain in the stack and garner, belongs to this family, together with the larvae or maggots found so often in chestnuts, acorns, hickory-nuts, and filberts; as well as unripe plums, apricots, peaches, and cherries. The destruction of fruit occasioned annually by these species which bore into fruits and occasion them to fall from the tree before ripening, is so great as to make it a matter of great importance to acquire the most accurate knowledge in regard to the appearance and habits of these insects, as the only means by which their effects can be counteracted. Often in gardens and orchards, trees loaded with young plums lose the whole of their fruit from the defrayment of grubs, which have been ascertained by naturalists to be the larvae or young of a small beetle of the weevil tribe, called the Neunaphar, or plum-weevil, and still more commonly in the United States, the curculio. Dr. Harris states that he has found the beetles in Massachusetts as early as the 30th of March, and as late as the 10th of June, and at various intermediate times, according to the advanced or retarded state of vegetation in the early part of the season. He has frequently caught them flying in the middle of the day. “They are from three-twentieths to one-fifth of an inch long, exclusive of the curved snout, which is rather longer than the thorax, and is bent under the breast, between the forelegs, when at rest. Their colour is a dark brown, variegated with spots of white, ochre-yellow, and black. The thorax is uneven; the wing-covers have several short ridges upon them, those on the middle of the back forming two considerable humps, of a black colour, behind which there is a wide band of ochre-yellow and white. Each of the thighs has two little teeth on the under side. They begin to sting the plums as soon as the beetle is set, and, as some say, continue their operations till the first of August. After making a suitable puncture with their snouts, they lay one egg in each plum thus stung, and go over the fruit on the tree in this way till their store is exhausted; so that where these beetles abound, not a plum will escape being punctured. The irritation arising from these punctures, and from the gnawings of the grubs after they are hatched, causes the young fruit to become gummy, diseased, and finally to drop before it is ripe. Meanwhile the grub comes to its growth, and, immediately after the fruit falls, burrows into the ground. This may occur at various times between the middle of June and of August; and in the space of a little more than three weeks afterwards, the insect completes its transformations, and comes out of the ground in the beetle form. The history of the insect thus far, is the result of Dr. Harris’s own observations; the remainder rests on the testimony of other persons. “In an account of the plum-weevil, by Dr. James Tilton of Wilmington, Delaware, published in Mease’s ‘Domestic Encyclopedia,’ under the article Fruit, and since republished in the ‘Georgical Papers for 1809,’ of the Massachusetts Agricultural Society, and in other works, it is stated, that peaches, nectarines, apples, pears, quinces, and cherries, are also attacked by this insect, and that it remains in the earth in the form of a grub, during the winter, ready to be matured as a beetle, as the spring advances. These statements,” says Dr. Harris, “I have not yet been able to confirm. It seems, however, to have been fully ascertained by Professor Peck, Mr. Say, and others, in whose accuracy full confidence may be placed, that this same weevil attacks all our common stone-fruits, such as plums, peaches, nectarines, apricots, and cherries; Dr. Burnett has recently assured me that he has seen this beetle puncturing apples; and it is not at all improbable that the transformations of some of the grubs may be retarded till the winter is passed, analogous cases being of frequent occurrence. Those that are sometimes found in apples must not be mistaken for the more common apple-worms, which are not the larvae of a weevil. The Rev. F. V. Melsheimer remarks in his Catalogue, that this insect lives under the bark of the peach tree. Professor Peck raised the same beetle from a grub found in the warty excescence of a cherry tree, and from this circumstance named it Rhynccheus cerasi, the cherry-weevil. The plum, still more than the cherry tree, is subject to a disease of the small limbs, which shows itself in the form of large irregular warts, of a black colour, as if charred. Grubs, apparently the same as those that are found in plums, have often been detected in these waris, which are now generally supposed to be produced by the punctures of the beetles, and the residence of the grubs. Professor Peck says that the seat of the disease is in the bark. The sap is diverted from
Its regular course, and is absorbed entirely by the bark, which is very much increased in thickness; the cuticle bursts, the swelling becomes irregular, and is formed into black lumps, with a cracked, uneven, granulated surface. The wood, besides being deprived of its nutriment, is very much compressed, and the branch above the tumour perishes. The grubs found by Professor Peck in the tumours of the cherry-tree, went into the ground on the sixth of July, and on the thirtieth of the same month, or twenty-four days from their leaving the bark, the perfect insects began to rise, and were soon ready to deposit their eggs in healthy branches. (See Professor Peck's account of Insects which affect Oak and other trees in a plate; in the Massachusetts' Agricultural Repository and Journal, vol. v. p. 312.) (Harris.)

In order to account for the occurrence of these insects both in the fruit and in the branches of the trees, Dr. Harris ventures the following explanation, although it rests only upon conjecture. The final transformation of the grubs, living in the fruit, appears to take place at various times during the latter part of summer and the beginning of autumn, when the weevils, finding no young fruit, are probably obliged to lay its eggs in the small branches. The larvæ or grubs from these eggs live in the branches during the winter, and are not perfected till near the last of the following June. Should the fall of the fruit occur late in the autumn, the development of the beetles will be retarded till the next spring; and this I suppose to be the origin of the brood which stings the fruit. These suggestions seem to receive some confirmation from the known habits of the copper-plum weevil of Europe, which, "in default of plums, make use of the soft spring shoots of the plum and apricot trees." (Kollár's Treatise, p. 233.)

"It has been noticed, that trees situated in lanes and extensive yards, where numerous cattle are confined, generally escape the attacks of the curculio. This is supposed to be in part owing to the ground being trodden so hard as to render it difficult for the worm to enter the earth, and to the annoyance and fright to which this timid insect is subjected, by the cattle rubbing against the trees. The insects, according to Dr. Tilton, in such cases of fright, roll themselves into a little ball, and fall to the ground, where they become liable either to be trodden to death, or devoured by the farm-yard poultry as a delicious morsel. Poultry of all species have been recommended as very useful, from the multitudes of insects they devour, they being particularly fond of the beetle tribe."

"A case is mentioned by Dr. Tilton (see Dom. Encyc.), of Colonel T. Forest, of Germantown, who, having a fine plum tree near his pump, tied a rope from the tree to his pump handle, so that the tree was gently agitated every time there was occasion to pump water. The consequence was, that the fruit on this tree was preserved in the greatest perfection." Hogs are stated to be extremely useful in orchards, by devouring at once the fallen fruit and the insect which it contains. And provided the hogs are sufficiently numerous to devour every fallen fruit, they will shortly exterminate the insects from the orchard in which they are permitted to roam.

"Paving the ground is said to be a most effectual mode of preserving fruit from the attacks of the curculio. By presenting its descent into the earth, it finds no winter habitation. The ground should first be well manured, and the whole surface well paved with the common stones which so often encumber the fields. The trees, in this case, may be set very close. The excess of rain being carried off by the pavement, and their luxuriance being thus restrained, such trees must not only produce great crops, but from the effect of the sun on the naked pavement, the fruit must be of the finest quality."

"Another and ingenious mode of destroying the curculio has lately been devised by Dr. Joel Burnet, of Southboro', Massachusetts, and in the single instance only, in which he has tried the experiment, it has proved completely successful. There stood in his garden a young plum tree of the prince's imperial gage, which was filled with blossoms every year, but bore no fruit. Early in spring, a hen, with an early brood of chickens, was placed in a coop beneath the tree. Thus were all the curculiones destroyed in the interval, soon after they arose from the earth, and before they had recovered strength sufficient to take to their wings or ascend the tree. This plum tree, in that year, bore, in consequence, a very large crop of fruit. He observed that the curculio often ascended by aid of its wings." (Kenrick's American Orchardist.)

The wings of the curculio, plum, or cherry-weevil are so small as to assist it in climbing, but not to enable it to fly to a distance. This explains the reason why trees standing so near each other as almost to interlace their branches will some escape, whilst others lose all their fruit.

Col. Forest's remedy may be partially applied by shaking the trees suddenly and briskly so as to produce a jar that will extend among the branches. This may be done morning and evening, and as much oftener as convenient, during the time when the weevils or beetles are engaged in stinging the fruit. Those which fall may be gathered in a sheet and thrown into the fire. All the fallen wormy plums should be immediately gathered and given to hogs, or, when this is not convenient, boiled or steamed, so as to kill the enclosed grubs. Diseased excrescences should be cut out and burned every year before the last of June. The moose-plum tree (Prunus Americana), Dr. Harris says, seems to escape the attacks of insects, since no warts are found upon it, even when growing in the immediate vicinity of diseased foreign trees. It would, therefore, he thinks, afford the best stocks for budding or engraving upon. It can easily be raised from the stone, and grows rapidly, but does not attain a great size. This might secure the body of the tree, but it is evident that the branches, being of different wood, must be exposed to the attacks of the weevil. See May Beetles, p. 173. (The 18th vol. of the "New England Farmer" contains a paper upon this insect, by Dr. Burnett, which may be read with advantage.)
CURD. The coagulum of milk, from which cheese is made. See CHEESE.

When milk sours, free acetic acid is formed, and by its action the coagulation of the casein part of the milk takes place; rennet causes the same effect in milk which is not sour, which probably depends on the gastric fluid in the rennet. Curd is a white, insipid, inodorous substance, insoluble in water, but soluble in alkalies. By alcohol it is converted into a substance like spermaceti, which gives out a very fetid odour.

When dry curd procured from sour milk is well washed, and then mixed with its own bulk of alcohol, and the soluble matter filtered and separated from the insoluble, and thickened by gentle evaporation, it becomes viscid, and forms an excellent cement for glass and china.

CURING BEEF and PORK. See SALTING.

A report of the committee for the premium offered for curing beef and pork, appears in the Trans. High. Soc. vol. v. p. 56.

CURNANT. The fruit of two species of Ribes, viz., R. rubrum, which furnishes the common red and white currants, and R. nigrum, which produces the black currant. There are five or six species of this indigenous plant. The rock currant (R. petraeum), the acid mountain currant (R. spicatum), and the tasteless mountain currant (R. alpinum), all grow wild in woods in the north of England; and the common red and black currants are also found wild in many parts of the country, but their fruit is insipid. The pale currant is a variety between the red and white.

The white, black, and red currant ripen their berries very early in July, in which month the fruit jelly should be made. All the currants may, by being matted, be preserved till the middle of winter, and on north walls and shaded situations sometimes hang, and are good till the end of November. They will thrive on almost any soil; but their fruit is more savoury when produced in a dry and open ground. They are very easily propagated by planting slips or cuttings at any time from September to March. After standing about two years, they will be fit to be removed to those places where they are intended to remain.

The currant, one of the most wholesome and grateful of fruits, has medicinal properties. Red currants are very cooling in fevers. They quench thirst, and create appetite. When the fruit is not to be had fresh, red currant jelly, mixed in water, is equally refreshing. Black currants are useful in sore throats. (Brande's Diet.; Phillip's Fruits; Willich's Dom. Encyc.; Eng. Flor., vol. i. p. 330.)

In addition to the varieties of gooseberries (Ribes vagum crispum) and currants met with in gardens, seventeen or eighteen additional species are found in the United States. A black currant resembling those in gardens grows wild in Pennsylvania, whilst a red species on a trailing vine is found in the northern counties. See GOOSEBERRY.

CURRANT-BUSH BORER. An insect caterpillar belonging to the genus Ageria. See CATERPILLARS.

CUSHAT. A local name for the ring-dove, supposed to be derived from the Saxon cusseate, from curse, chaste, in allusion to the conjugal fidelity of this bird.

CUSTOMS OF COUNTRIES. With regard to the usual relation of landlord and tenant in England, these vary considerably. But in cases where there is a written agreement, no inquiry can be made as to the custom of the county (Liebenrood v. Vines, 1 Mer. 15); and when an express stipulation is made, the custom of the county is excluded entirely. (Roberts v. Parker, 1 C. & M. 808.) The following epitome of usages in a few counties, chiefly abridged from the work of Kennedy and Grainger on the Tenancy of Land, must, of course, be regarded as having only a very general application.

Bedford.—The tenant commonly enters, in this county, at Michaelmas, some at Lady-day. Leases seven years. Rents paid half-yearly. Tenant generally restricted from breaking up pastures, or selling hay and straw, quitting at Michaelmas, is at liberty to plough and sow wheat, if at Lady-day; then may sow spring-grain till day of quitting; but in either case has the option to do it himself or let his successor do it. When the ouergoer sows, they are assessed to the incoming so as to include all labour; has barn allowed him, but cannot carry away straw. Incomer takes all dung found on premises free of charge; but pays for grass-seeds, and that of the labour, and for fallow-ploughing, or spring-ploughing, which his predecessor, quitting at Lady-day, had not time to sow; but with respect to any fallow, either for wheat or turnips, when the ouergoer takes the crop, there is no demand made upon the incoming tenant.

Berks.—Farms commonly lease for 7 or 14 years from Michaelmas, entering to plough followes at Lady-day: from which time the incomer has part of the house allowed him, and room for one team; the ouergoer retains the rest of the premises till May-day or Midsummer. The rents are commonly paid half-yearly, and in general there is no restraint upon the tenant's cultivation, except that he covenants to leave a stated number of acres for fallow. Usually he has power of selling hay and wheat straw, although in other portions of the county only to exchange it for dung. Wheat straw he must leave to his successor as well as the hay. Incomer has to pay for clover or other grass-seeds, the seed, and labour, and hay-crop, at a feeding-out price.

Carmarthen.—Farms were here formerly let upon leases for three lives; but terms of 14 years are now more common. The entry is made upon both house and land at Michaelmas. The tenant is under no restriction, cultivates as he pleases, and sells hay, straw, and dung.

Cheshire.—Farms let upon leases, but many only by the year, and this is a much more common practice than formerly. Tenant takes from Candlemas, but only gets possession of the house at May-day. The tenant is commonly restrained from having more than a given proportion of land, usually one-third, under plough. This portion, however, he may.
CUSTOMS OF COUNTIES.

Cumberland.—Tenants enter at Lady-day into the farm, but not into the house till May-day. Leases commonly for three, seven, or nine years. The tenant commonly bound to plough the land in such proportions that a certain part may remain in grass for three years. It is prohibited from having two white crops in succession, and must leave as much land sown with grass-seeds as he found on the farm. Cannot sell hay or straw, and must apply not less than sixty busses of lime per acre for his wheat or turnips after a fallow. The outgoing tenant retains possession of the house and premises for cattle till May-day. Is paid for whatever crops he leaves which he himself paid for when he took the farm. Leaves all the straw and manure for the incoming tenant.

Derby.—Tenants chiefly yearly tenants from Lady-day. The land almost entirely pasturage. The tenant is usually restricted from breaking these up without permission, even if he lays down arable land in lieu of it. He cannot sell either hay or straw. The outgoing tenant is not paid for either manure or straw; he always sows the wheat, but is not paid for any fallows or ploughings which may have been done at his expense to promote the growth of it. He receives, however, two-thirds of the wheat if a fallow crop, or one-half if a brush crop, and for the seed crops he is allowed for seed and labour.

Devon.—In the west, entry at Michaelmas; in the east at Lady-day, with privilege of entry on the land at Midsummer to prepare for wheat. The tenant usually restrained from taking more than two white crops for a fallow, or sowing two wheat crops successively, without a fallow or green crop between them. Must use a certain quantity of lime per acre for his barley or wheat crop, and leave the same quantity of land for wheat at the expiration of his lease that he found on taking possession. He has the liberty of selling hay and wheat straw, and at the end of his lease he also. A Lady-day holder receives from his successor the value of the wheat upon the ground, and the young clovers or other grass seeds by valuation. A Michaelmas tenant can only receive the value of the seeds; but in either case he freely leaves all the dung for his successor.

Essex.—The farmer in Essex commonly holds by leases of 7 or 14 years; entry at Michaelmas, both of house and land. He usually covenants to farm on the four-shift system, dressing and fallowing after every third crop, and never to take two white crops in succession: on pasture land, however, he is commonly unrestrained. He may carry also hay or straw, but for every load of either he is bound to bring back a load of dung, and near London two loads are required for every load of straw, and one for every load of hay.

The outgoing tenant sows the Michaelmas crop and is paid by valuation for one year's improvement, which includes the labour, the seed, and the manure he has laid out upon the ground from the preceding Michaelmas. He is allowed for the seeds, for ploughing, harrowing, and rolling, which a summer fallow has undergone, for the manure laid on, and for the carting of it, and for all the unspread dung, or other manure on the farm. The outgoing tenant has the use of the barns for his crop. The incoming claims the straw and chaff on condition of his threshing the corn, and carrying it to market. The incoming has the Michaelmas crops, the hay, turnips, and young seeds valued to him, with all the seed, labour, and manure bestowed upon them.

Hertford.—Leases 7 or 14 years from Lady-day. Mode of cultivation varies; sometimes two crops and a fallow, in others, the four-course system. The tenant may sell hay and wheat straw, but no other straw. The outgoing tenant takes an offgoing crop of both spring and Michaelmas crops, and pays for the ground upon which they stand upon the premises. He must use, however, the last year's straw upon the premises, and he leaves all the dung for the incoming tenant.

Kent.—Much of the land of Kent, as in other counties, is held by the year, but a larger portion is rented under leases of 7 to 14 years; the tenant entering at Michaelmas.

The farmer is usually restrained from selling hay or straw; or, if he is allowed to dispose of them, it is on condition of his bringing on to the farm a certain quantity. He is usually not much restricted in his mode of cultivation. He is commonly prevented from having more than two white crops to a fallow.

The outgoing tenant threshes his last crop, and sells the straw to the incoming tenant; and if he is obliged to feed the hay upon the premises, this is commonly valued also at a feeding out price. He is paid also for the labour bestowed upon the summer fallows, which he has the privilege of sowing up to the time of his quitting the farm; he is also paid for the seed and labour both for the turnips and the grasses; for the whole of the manure, and labour of carting and spreading the manure of the last...
year, and for half of the preceding. These, with the hop-poles, make the payments required of an incoming tenant rather heavy.

Leicester is chiefly farmed by yearly tenants, who enter at Lady-day, and occasionally at Michaelmas. They are not allowed to break up their pastures or sell either hay or straw. Sometimes they engage to lay an annual amount of lime on the land.

The outgoing tenant is paid for all clear fallsows, for which he is allowed three ploughings; but if he has taken a greater number of fallsows, he receives nothing. For the outgoer, if it has been sown on a clear fallow, for instance—he is allowed for seed and labour, and for the ploughings, but otherwise only for seed and labour. He is allowed for his seed crop, labour, and seed; but nothing for a turnip fallsow, either fed or pulled; if he leaves at Michaelmas, however, he is allowed for his turnips one year’s rent. The incoming cannot enter to plough without permission till Lady-day.

Lincoln.—Farmers commonly held by lease of from 7 to 14 years from Lady-day. The tenant is usually restrained from selling either hay or straw, or from taking more than two white crops to a fallow. These restrictions, however, do not apply to the fen land.

The outgoing tenant has commonly the right of sowing spring-grain until Lady-day, and of taking an off-going crop, both of wheat and other corn, all of which, however, he must trash on the premises. But a very common way is for the outgoing to be paid for all his crops, the value of seed and labour, and also for the manure. The crops are valued at harvest-time, and the price is set according to the average of three market-days, taken once a month, between harvest-time and the ensuing Lady-day.

Norfolk.—Farmers hold chiefly by leases of 7 or 14 years, some for 21, and they enter at Michaelmas. They generally covenant to farm on the four-course system, are often restrained from sowing above a certain number of tares and oats. This crop being considered to be much more impoverishing to the land than barley, he is not allowed to sell either hay or straw. The outgoing tenant either threshes his harvest himself, or he agrees with his successor, who carries out the grain and keeps the straw and chaff; the incoming pays for the growing crops on the ground, but not for the labour; thus, if the turnip crop fails, he receives nothing for the labour. He sows the wheat crop, but he cannot enter the farm before Michaelmas; to do this without leave, he has to pay for the hay on the farm; but he takes the dung free.

Nottingham is cultivated chiefly by yearly tenants, who enter at Lady-day. They are commonly not allowed to sell either hay or straw, not to take more than three crops to a fallow, and never two white ones in succession. When the incoming enters at Michaelmas, the outgoing is paid by valuation, either upon wheat or turnips, for all the seed and labour he has bestowed upon that crop, and for all the ploughing he has done before the time he quits; for all artificial manure, such as bones, &c., if for the first crop, then the full tillage; if the second, only half a tillage, and so on; but for dung in or on the land he is allowed nothing; but if he enters at Lady-day, then he is paid for both, for seed and for labour.

Salop.—Farms are generally held by yearly tenants, who enter at Lady-day; but on to the meadow land, in some places, at Candlemas, that he may water or manure. He is restrained from selling hay or straw, but not to any particular mode of cultivation. When he quits, he is allowed for his turnips, unless he leaves to the land within the last two years; the whole value for that of the last year, half the value for that of the preceding: he receives two-thirds of the value of the wheat crop, the value of the seed crops, but nothing for either fallows or dung. He cannot plough for fallows or spring crops without the authority of the incoming, who cannot enter himself to plough without leave before Lady-day.

Somerset.—Farmers have usually leases of 8 or 12 years from Lady-day, the outgoing retaining the wheat crop, threshing it on the premises, and leaving the straw, chaff, and dung for the incoming; and for this purpose he commonly holds on till the Midsummer twelvemonth after he quits possession. A tenant cannot sell either hay or straw, or take more than two white crops and a green one without a fallow. He is restrained from breaking up pastures, and he very commonly consents to spend annually a certain sum in lime or some other kind of manure. The incoming tenant sows the spring corn, but he cannot enter before Lady-day without leave from the outgoing.

Stafford.—The farmers in this county usually hold from year to year. The tenant is commonly restrained from selling either hay or straw, and there are very few restrictions of any kind as to the mode of cultivation. The outgoing tenant is usually paid for all the dung he leaves upon the farm, and for all clear summer fallows, but nothing for bastard fallows, even if the seeds or turnips are fed off. For all the wheat on a clean fallow, sown previously to his notice to quit, he receives two-thirds of the crop; if a brush crop, only one-half; but for all he sows after notice, only the value of the seed and labour. The incoming cannot enter to plough before Lady-day: he pays for both the dung and straw left on the farm.

Wexford.—Leases in this county are commonly granted for 7, 9, 11, or 21 years from Lady-day. The house, and one field, however, is usually retained till May-day: he has the privilege, however, of going upon the land at old Candlemas to plough for his fallow and spring crop.

The tenant is commonly restricted from having more than two white crops before he sows the land with seed, and that between the two white crops he is to have either a green one or a fallow. He is to manure his meadow ground once in three years, and leave the farm in the same working plight as he found it. The outgoing retains the house and one field till May-day, paying rent and taxes, however, for what he thus holds; with this exception, he is bound to free the land by the 6th of April. In the south of this county, the outgoing receives for the wheat crop on the ground, two-thirds if
CUT-WORM.

followed for, and one-half after a bastard fallow. He pays for this, however, no rent after the 6th of April. He may plough for barley and take half the crop, but not for any other spring crop.

Yorkshire.—In this great county, the customs vary with the Riding. In the W. R. the entry is Old Candlemas, or New Year's day. In the N. R. it is Lady-day: may go on to the land at Candlemas, and into the house at May-day. In the E. R. the entry is at Lady-day. In all three Ridings a yearly tenancy is the most common.

In the N. R. the outgoing tenant sows his wheat, and has an offgoing crop, which he may either trash himself, or sell to his successor or to a stranger; but he cannot carry away straw, but has barn and yard room to consume it on the premises until the following May-day twelvemonth.

The outgoer, however, cannot in the last year of his tenancy sow more than one-third of his land, but that third he may sow at whatever time and in whatever way he may think proper; for all the ground that he sows he pays a corn standage, that is, rent, till harvest time: if he sows more than his proportion, the incomer takes the crop, and the measurement is very nicely calculated. The incomer enters at Candlemas to plough for his spring crop and fallows: he takes the young seeds. In the upper part of the West Riding, the customs between the incomer and outgoer are the same as in the north; but below Abowth the customs are quite different, being, as the people say, “good ones to come out with, but bad ones to enter upon.” For there the outgoer sows the wheat crop, which the incomer is obliged to pay for, together with the grass-seeds, and to pay for the tillage and half tillage of those crops and on the turnips, and for all the manure laid upon the lands, or about the premises; the incomer who enters at Candlemas has two and a half year's manure, and one and a half year's tillage to pay for. In the East Riding, the outgoer sows the wheat crop and the spring corn, until Lady-day, and takes what he sows as an offgoing crop along with the wheat, paying no rent after Lady-day: he must trash them, however, on the premises, and leave the manure. An incomer has here only to pay for seeds. (Kennedy and Granger on Tenancy of Land.) See Appraisement.

CUT. In farricry, a hurt or clean wound made with any sharp-cutting instrument. The way of treating such an accident is to bring the two incised surfaces together, and bind them up, if possible, with a little lint or tow, without any balsams or spirituous applications being used.

CUT-WORM. In almost every section of the United States, great complaints are annually made of green crops destroyed or injured, more or less, by what is popularly termed the cut-worm. The young Indian corn is an especial sufferer; but several other plants having tender stems, such as beans and cabbages, are liable to be cut off near the ground, or just below the surface, when beginning to sprout. As all such mischief is ascribed to the cut-worm, it might be inferred that an insect thus spoken of in the singular number would be well known. And yet the opinions upon the subject of its identity, or how many species there may exist, are various and conflicting. After a toilsome search through many of the American agricultural publications, Dr. Harris says he became convinced that these insects and their history are not yet well known to some of the very persons who have suffered from their depredations. Various cut-worms, or under-ground or subterranean caterpillars, wire-worms, or Juli, grub-worms or the young of May-beetles, and even spindle or bud-worms, or the young of a species of moth called corn Gortyna, are often confounded together or mistaken for each other; sometimes their names are interchanged, and sometimes the same name is given to each and all of these different animals. Hence, the remedies that are successful in some instances are entirely useless in others. “The name of cut-worm,” says Dr. Harris, “seems originally to have been given to certain caterpillars that live in the ground about the roots of plants, but come up in the night, and cut off and devour the tender stems and lower leaves of young cabbages, beans, corn, and other herbaceous plants. These subterranean caterpillars are finally transformed to moths belonging to a group which may be called agroditians (Agrotidiae), from a word signifying rustic, or pertaining to the fields. Some of these rustie moths fly by day, and may be found in the fields, especially in the autumn, sucking the nectary of flowers; others are on the wing only at night, and during the day lie concealed in chinks of walls and other dark places. Their wings are nearly horizontal when closed, the upper pair completely covering the lower wings, and often overlapping a little on their inner edges, thus favouring these insects in their attempts to obtain shelter and concealment. The thorax is slightly convex, but smooth or not crested. The antennae of the males are generally beset with two rows of short points, like fine teeth, on either side of the head. The fore-legs are often quite spiny. Most of these moths come forth in July and August, and soon afterwards lay their eggs in the ground, in ploughed fields, gardens, and meadows. In Europe it is found that the eggs are hatched early in the autumn, at which time the little subterranean caterpillars live chiefly on the roots and tender sprouts of herbaceous plants. On the approach of winter they descend deeper into the ground, and, curling themselves up, remain in a torpid state till the following spring, when they two or three towards the surface, and renew their devastations. The caterpillars of the Agroditians are smooth, shining, naked, and dark-coloured, with longitudinal pale and blackish stripes, and a few black dots on each ring; some of them also have a shining, horny, black spot on the top of the first ring. They are of a cylindrical form, tapering a little at each end, rather thick in proportion to their length, and are provided with sixteen legs. They are changed to chrysalids in the ground, without previously making silk tubes. Different kinds in Europe are the caterpillars of the corn rust or winter dart-moth (Agrotis segetum), the
wheat dart-moth (Agrotis tritici), the eagle-moth (Agrotis aquilina), and the turf rustic or antler-moth (Charaes grominis). The first two attack both the roots and leaves of winter wheat; the second also destroys buckwheat; and it is stated that sixty bushels of mould, taken from a field where they prevailed, contained twenty-three bushels of the caterpillars; those of the eagle-moth occasionally prove very destructive in vineyards; and the caterpillars of the antler-moth are notorious for their devastations in meadows, and particularly in mountain pastures.

"The habits of our cut-worms appear to be exactly the same as those of the European Agrotidians. It is chiefly during the months of June and July that they are found to be most destructive. Whole corn-fields are sometimes laid waste by them. Cabbage-plants, till they are grown to a considerable size, are very apt to be cut off and destroyed by them. Potatoes, vines, beans, beets, and various other culinary plants suffer in the same way. The products of our flower-gardens are not spared; asters, balsams, pinks, and many other kinds of flowers are often shorn of their leaves and of their central buds, by these concealed spoilers. Several years ago I procured a considerable number of cut-worms in the months of June and July. Some of them were dug up among cabbage-plants, some from potato-hills, and others from the corn-fields and the flower-garden. Though varying in length from one inch and a quarter to two inches, they were fully grown, and buried themselves immediately in the earth with which they were supplied. They were all thick, green-grey-looking caterpillars, of a dark ash-yellow colour; but I neglected at first to examine them carefully in order to see if they were marked exactly alike. Some of the last found were observed to have one or two blackish stripes on each side of the body, and a pale stripe on the body, with four little black dots on each wing. These last were also blackish. They were soon changed to chrysalids, of a shining mahogany-brown colour; and between the 20th of July and the 18th of August they came out of the ground in the moth state. Much to my surprise, however, these cut-worms produced five different species of moths; and, when it was too late, I regretted that they had not been more carefully examined, and compared together before their transformation.

The largest of these moths expanded its wings more than two inches, and bore a close resemblance to one called in Europe the dark sword rustic (Agrotis suffusa). Dr. Harris named the American moth the lance rustic, (Agrotis telifera), and gives the following description of it.

"The fore-wings are light brown, shaded with dark brown along the outer thick edge, and in the middle also in the female; these wings are divided into three nearly equal parts by two transverse bands, each composed of two dark brown lines; in the middle space are situated the two ordinary spots, together with a third oval spot, which touches the anterior band; these spots are encircled with dark brown, and the kidney-spot bears a dark brown lance-shaped mark on its hinder part; the hindmost third of the wing is crossed by a broad pale band, and is ornamented by a narrow rowy or festooned line, and several small blackish spots near the margin. The hind-wings are pearly white, and semi-transparent, shaded behind, and veined with dusky brown. The thorax is brown or gray-brown, with the edge of the collar blackish. The abdomen is gray. The wings expand two inches or more." (Harris's Treatise on Insects, 15th Ed., 10th Ser., 137.)

Two other species resemble the one just described, and are counterparts of European species. The fourth is the smallest of the five, expanding its wings an inch and a quarter. The fore-wings are dark ash-coloured, exhibiting very faint traces of the transverse wavy lines or bands more or less distinctly visible on the other species. The two ordinary spots are large and pale, and alternate, with a triangular and a square deep black spot. The hind-wings are brownish-gray in the middle, and blackish behind. Dr. Harris calls this last the checker rustic (Agrotis tessellata).

The fifth species answered very well to the description of the American cabbage cut-worm, described by Mr. J. P. Brace, in the first volume of Silliman's "American Journal of Science," and somewhat resembles Dr. Boisduval's figures of a European moth called Agrotis latius. The fore-wings are of a dark ash colour, with a lustre like satin; they are crossed by four whiteish bands, edged on each side with black. There is a transverse row of white dots, followed by a row of black, arrow-shaped spots, between the third and fourth bands, and three white dots on the outer edge near the tip; the ordinary spots are edged with black and white. The hind-wings are light brownish-gray, almost of a dirty white in the middle. The head and thorax are chinchilligray, and the abdomen is coloured like the hind-wings. The wings expand from one and five-eighths to one inch and three-quarters. This kind of moth is very common between the 10th of July and the middle of August. Like all the foregoing species, it flies only at night. According to Mr. Brace, this moth lays its eggs in the beginning of autumn, at the roots of trees, and near the ground; the eggs are hatched early in May; the cut-worms continue their depredations about four weeks, then cast their skin and become narrow, wavy whitish bands, in the earth, a few inches below, the surface of the ground; the pupa state lasts four weeks, and the moth comes out about the middle of July; it conceals itself in the crevices of buildings and beneath the bark of trees, and is never seen during the day; about sunset it leaves its hiding-place, is constantly on the wing, is very troublesome about the candles in houses, flies rapidly, and is not easily taken. From what is known respecting the history of the other kinds of Agrotis, and from the size that the cabbage cut-worms are found to have attained in May, I am led to infer that they must generally be hatched in the previous autumn, and that, after feeding a while on such food as they can find immediately under the surface of the soil, they descend deeper into the ground and
remain curled up, in little cavities which each one makes for itself in the earth, till the following spring."

Such are the descriptions given by the naturalists of the cut-worms and their moths found in the Eastern States. We wish it was in our power to furnish as much accurate information upon the cut-worms found in the other portions of the United States, provided any essential differences exist. The deficiency, so far as a portion of the Middle States is interested, has been supplied in a great measure through the researches of Dr. F. E. Melsheimer, of York county, Pennsylvania, who, in a communication made to Dr. Harris, gives the following information.

"There are several species of Agrotis, the larvae of which are injurious to culinary plants; but the chief culprit with us is the same as that which is destructive to young maize. The corn cut-worms make their appearance in great numbers at irregular periods, and confine themselves in their devastations to no particular vegetables, all that are succulent being relished by these indiscriminate devourers; but, if their choice is not limited, they prefer maize plants, when not more than a few inches above the earth, early-sown buckwheat, young pumpkin-plants, young beans, cabbage-plants, and many other field and garden vegetables."

"When first disclosed from the eggs they sub-

sist on the various grasses. They descend in the ground on the approach of severe frosts, and reappear in the spring about half-grown. They seek their food in the night or in cloudy weather, and retire before sunrise into the ground, or beneath stones or any substance which can shelter them from the rays of the sun; here they remain coiled up during the day, except while devouring the food which they generally drag into their places of con-

cealment. Their transformation to pupae oc-

curs at different periods, sometimes earlier sometimes later, according to the forwardness of the season, but usually not much later than the middle of July."  "The moths, as well as the larva,

vay much in the depth of their colour, from a pale ash to a deep or obscure brown. The ordinary spots of the upper wings of the moth are always connected by a blackish line; where the colour is of the deepest shade these spots are scarcely visible, but when the colour is lighter they are very obvious." This moth, Dr. Harris informs us, is very abundant in the New England States, from the middle of June till the middle or end of August. The fore-

wings are generally of a dark ash-colour, with only a very faint trace of the double transverse wavy bands that are found in most species of Agrotis. These expand one inch and three-

quarters. When shut they overlap and cover the back so flatly and closely as to allow the moth to creep into very narrow chinks and cre-
vices. During the day they lie hidden under the bark of trees, in the chimks of fences, and even under the loose clapboards of buildings.

When the blinds of houses are opened in the morning, a little swarm of these insects which, on the arrival of day, had crept behind them for concealment, is sometimes exposed, and suddenly roused from their beginning slumbers.

This kind of moth, Dr. Harris says, has the form and general appearance of some species of the genus Porophila. He has named it the clandestine quiet-moth.

The fact of the identity established by na-

turalists between this moth as found in New England and Pennsylvania, affords strong reason to infer that the same species of cut-

worms are to be met with over most, if not all, portions of the United States. Having thus described these insects under their various forms of destructive larvae or caterpillars, winged moths into which these are converted, and mentioned their times and sea-

sons of coming, going, and changing, so far at least as naturalists have traced these out,—we shall proceed to notice the remedies which have been tried and proposed to destroy them, or prevent their ravages.

Among the various means resorted to for the protection of Indian corn and other plants, is the soaking of the seed in copperas or other poisonous solution previous to planting or sowing. Rolling the seed in quick-time, or unbleached ashes, has also been recommended. Any one of these remedies may have some ef-

fect in protecting the seed against wire-worms (Idi) which only attack the grain or its root, but cannot answer against cut-worms which do not eat the seed or root, but penetrate the stalks. They may, how-

ever, as Dr. Harris observes, be of some bene-

fit by stimulating the young plant and pro-

mot ing its more rapid growth, by which it will be sooner placed beyond danger from the attacks of cut-worms. Fall-ploughing of sward-

lands, which are intended to be sown with wheat or planted with corn the following year, will turn up and expose the insects to the in-

cleney of the winter, whereby many of them will be killed. This will be destroyed at the time by birds. This remedy, however, may be objectionable in stiff clay soils, which would become very much packed or baked during the winter.

Among other remedies, one proposed by Mr. Park Shee of Delaware county, Pennsylvania, is said to be a simple and expeditious mode of destroying cut-worms. A pair of old wheels are to be fitted with projections like the cogs of a spur-wheel in a mill, which must be so formed as to make holes in the earth during the turning of the wheel, four inches deep. The smooth track which the wheels make on the soft ground, induces the worm in its noctur-

nal wanderings, to follow on till it tumbles into the pit. It cannot climb out, and is de-

stroyed by the hot sun.

The only effectual remedy at present known, Dr. Harris thinks, consists in turning a suffi-

cient force into the fields infested, to scratch up and destroy the worms by hand. This may require several days, but will generally be successful in securing the crop, when replant-

ing is performed at the same time. Estimates of the cost of labour and time thus expended,
show that the farmer is a great gainer by the 
outlay.
Mr. Deane once prevented the depredations of cutworms in his garden by manuring the soil with sea-mud. The plants generally escaped, although every one was cut off in a spot of ground contiguous. He acknowledges, however, that the most effectual remedy, even in field culture, is to go round every morning and open the earth at the foot of the plant, where, if present, the worm will be found at the root, within four inches of the surface. Mr. Preston of Rockport, Pennsylvania, protected his cabbage-plants by wrapping a hickory or walnut leaf around the stem between the root and leaves before planting. A piece of rag would answer equally well; but care must be taken to remove any such bandage when the plant has attained a size to resist the attacks of worms. Paper has been successfully used for this purpose by Mr. Fiske of Massachusetts.

Salt is known to be highly obnoxious to naked worms and caterpillars. Some farmers have found great protection from the depredations of these by mixing salt with the manure put upon the ground as mentioned by Mr. Colman in his "Third Report," where, however, no definite proportion is stated. Some Pennsylvania farmers place the greatest reliance in a mixture of equal parts of salt, ashes, and plaster of Paris, about a gill of which mixture is applied on each corn hill. The experiment has been tried on alternate rows which were exempt from the attacks of worms, whilst the rows to which no application was made suffered greatly. The plaster might probably be dispensed with.

Dr. Harris describes another naked caterpillar which is often found to be injurious to cabbages, cauliflowers, spinach, beets, and other garden vegetables with succulent leaves. It does not conceal itself in the ground, but lives exposed on the leaves of the plants which it devours. It is of a light yellow colour, with three, broad, longitudinal, yellow stripes, one on each side, and the third on the top of the back; and the head and feet are tawny. Dr. Melsheimer calls it the zebra-caterpillar, on account of its stripes. It comes to its full size in Massachusetts in September, and then measures about two inches in length. Early in October it leaves off eating, goes into the ground, changes to a shining brown chrysalis, and is transformed to a moth about the first of June. It is probable that there are two broods of this kind of caterpillar every summer, in some, if not all, parts of this country; for Dr. Melsheimer says that it appears in Pennsylvania in June, goes into the ground and is changed to a chrysalis towards the end of June or the beginning of July, and comes forth in the moth state near the end of August. The moth may be called Mamestra pieta, the painted Mamestra, in allusion both to the beautiful tints of the caterpillar, and to the softly blended shades of dark and light brown with which the forewings of the moth are coloured. It is of a light brown colour, shaded with purple brown; the ordinary spots on the fore-wings, with a third oval spot behind the round one, are edged with gray; and there is a transverse zigzag gray line, forming a distinct W in the middle, near the outer hind margin. The hind-wings are white, and faintly edged with brown around the tip. It is evident that this insect cannot be included in either of the foregoing groups of the owlet-moths. It belongs to a distinct family, which may be called Mamestridae, or Mamestrians. The caterpillars in this group are generally distinguished by their bright colours; they live more or less exposed on the leaves of plants, and transform in the ground. The moth flies by night only; most of them have the thorax slightly crescent-shaped, and the yellow, easily known by the zigzag line, near the outer hind margin of the fore-wings, forming a W or M in the middle.

As the caterpillar of the painted Mamestra does not seek concealment, it may easily be found, and destroyed by hand." (Harris) See GREGG, WIRE-WORMS, SPIDLE OF BUD WORMS.

CUTTING. When a horse cuts or wounds one leg with the opposite foot. The best remedy is to put on the cutting foot a shoe of even thickness from heel to toe, not projecting in the slightest degree beyond the crusp, and the crusp itself to be rasped a little at the quarters. This shoe should only have one nail on the inside, and that almost close to the toe. (Lib. Useful Know., The Horse, pp. 353, 341.)

CYDER. See CIDER.

CYNOSURUS. The dog's tail grass, from kæse, a dog, and cepa, a tail. There are at least three commonly known varieties of this grass in England, and two in the United States. One of which was found by Mr. Nuttall in the plains of Missouri. Very little value is attached to this grass by the American farmer.

Cynosurus cristatus. Crested dog's tail grass. Pl. 6, f. This is an excellent sheep grass. Sinclair found the produce per acre, from a brown loam with manure, at the time of flowering, to be 6125 lbs., containing nutritive matter 406 lbs. He says of it, "In all the most celebrated pastures, which I have examined, it constituted a very considerable portion of the produce."

Cynosurus cruciformis. Linear-spired dog's tail grass, flourishes best on a rich deep loam; next best on a clayey loam; in which soil Sinclair obtained of this grass, when in flower, 6806 lbs. per acre, containing nutritive matter 365 lbs.

Cynosurus echinatus. Rough dog's tail grass. It is a scarce, and an inferior grass. When in bloom, it yielded Sinclair per acre from a sandy loam 3445 lbs., containing of nutritive matter 191 lbs. (Paxton's Bot. Dict.; Sinclair's Hort. Gram. Wob.)

CYPERUS (Cypreus-grass). This is a natural order, embracing some of the sedge tribe somewhat allied to grasses. The stems are either solid or filled with a spongy pith-like substance, generally without joints, or nodes, tapering, cylindrical, or angular (often triangular), and the sheaths of the leaves which enclose the stem are not slit but entire. The roots of some species of cyperusses possess an aromatic odour, especially those of the C. longus. A few others produce tubers said to

32
of this mighty stream, form a vast expanse of waters. In Louisiana, those parts of the marshes where the cypress grows almost alone are called Cypriviers, cypress swamps, and they sometimes occupy thousands of acres.

In the deep, miry soil of the swamps in the Southern States, the bald cypress attains its utmost development, rising sometimes to the height of one hundred and twenty feet, with a circumference of twenty-five and even forty feet, at the conical base, which, at the surface of the earth, is always three or four times as large as the continued diameter of the trunk. On this account, in felling them the negroes are obliged to raise themselves upon scaffolds five or six feet above the ground. The base is generally hollow for three-quarters of its bulk. The summit is not pyramidal like that of spruces, but is widely spread and even depressed or drooping upon old trees. The foliage is open, light, and of a fresh and agreeable tint, the leaflets being small and fine. In autumn they change from a light green to a dull red, and are shed soon after. Boiled during three hours in water, they afford a fine, durable cinnamon colour. To bunches of very minute flowers, succeed cones about the size of the plum; round, firm and unbroken in the surface, filled with irregular seeds containing cylindrical kernels. The seeds retain their productive virtue for two years.

The stocks which grow in places where for half the year they are surrounded with three or four feet of water, have the bark lighter coloured than trees not so much exposed to water. Hence they are called White Cypress, whilst those less exposed to water, and having browner bark, and heavier, more resinous, and darker wood, are named Black Cypress. When destined to be employed in the arts, both kinds should be felled in winter, and kept a sufficient length of time for the wood to become perfectly dry. The wood of the cypress is far more durable than that of the pine, and is especially useful for making shingles to cover buildings of all kinds. Cedar rails for post and rail-fences are also in great demand in every portion of the Middle States where the oak and chestnut trees have become scarce. A large trade in cedar shingles is carried on between the southern parts of Norfolk, Wilmington, &c., with the West Indies.

It would be unwailing, says Michaux, to recommend the preservation and multiplication of the cypress in the maritime districts of the Carolinas and Georgia, though for an extent of more than nine hundred miles they have neither stone nor slate for building; it becomes daily more profitable for the increasing population to convert the marshes into rice-grounds, which afford a sure subsistence to the inhabitants and swell the mass of exported produce. Instead of wood, the houses will be constructed of brick, which is already beginning to be done, and covered with slate imported from the Northern States or from Europe. It is highly probable that in less than two centuries, the cypress will disappear from the Southern States.

The White Cedar (Cypressus thyoides) is one of the commonest trees in the eastern United States, and is used almost everywhere for shingles, laths, and almost every article of common use. The cypress is also one of the most magnificent trees of North America. It is found from Nova Scotia to Florida, and from the Atlantic to the Mississippi River. It grows in swamps and marshes, and is propagated by the seed. The wood is hard, close, and durable, and is used for building, furniture, and most of the common articles of wood. The bark is sometimes reduced to a powder and used as a substitute for paper. The leaves are long, narrow, and pointed, and the flowers are small, white, and inconspicuous. The fruit is a small, hard, astringent capsule, containing the seeds. The cypress is a very valuable tree, and is used extensively for building and other purposes.
of the most interesting trees in the United States for the varied utility of its wood. It grows only in wet grounds. In New Jersey, Maryland, and Virginia, it nearly fills the extensive marshes which lie adjacent to the salt meadows, and are exposed in high tides to be overflown by the sea. Farther south, it is mingled with the cypress, by which it is at length entirely supplanted. The white cedar is not to be mistaken for the white cypress, a variety of the bald cypress. In lower Jersey and Maryland, the swamps in which the white cedar grows, are only accessible during the driest periods of summer, and whilst frozen in winter. The trees stand so thick in these swamps that the light can hardly penetrate the foliage. The white cedar grows seventy or eighty feet high, and rarely more than three feet in diameter, unless perhaps in the Great Dismal Swamp, near Norfolk, where it flourishes in company with the bald or black cypress. When the white cedars are close and compressed, the straight and perpendicular trunks are free from branches to the height of fifty or sixty feet. They are observed to choose the centre of the swamps, and the cypress the outside.

The foliage is evergreen, each leaf consisting of a little branch numerously subdivided, and the flowers, which are scarcely visible, produce very small rough cones of a greenish tint, which changes to bluish towards the fall, when they open to release the fine seeds.

The wood is light, soft, fine-grained, and easily worked. When perfectly seasoned and exposed some time to the light, it is of a rosy hue. It preserves its aromatic odour for a very long time, when kept dry, and resists the destructive tendencies of alternate moisture and dryness longer than any other wood, for which quality shingles made of it are preferred in Baltimore and Philadelphia to those of the bald cypress. In the first named city they are generally called juniper shingles. They will last on a roof for thirty or thirty-five years. The great domestic consumption and exportation has raised the price of cypress shingles from four and five dollars per thousand in 1808, to thirty or forty dollars per thousand in 1842. Swamps producing white cedar, so useful for fence timber and other important purposes, constitute a valuable species of property. (Michaux.)

D. DACTYLIS. A genus of grasses which, with one exception, are of but little value for cultivation. See Cock's-foot Grass.

Dairy. The place where milk is kept, and butter and cheese prepared and preserved. The proper construction and management of a dairy are questions of considerable importance to the farmer. It should be situated, if possible, on a dry porous soil. The room should be made of brick or stone, with a floor of the same materials, for the sake of its being more readily and frequently washed with cold water, not only on the score of cleanliness, but that the temperature of the place may in sum-
DAIRY.

besimilk butter will injure a whole firkin. The practice of scalding cream in cold weather should also be avoided, as cream thus treated will never make good butter. 8. Great care should be taken not to steep the firkins, or other dairy vessels, in boggy or unwholesome water; only the purest spring or clear running water should be used. 9. Old butter should never be mixed with new.

Lime-tree yields perhaps the best wood for butter firkins; and the St. Ubes' Bay or marine sweet salt, free from buttern, is the best salt to use for dairy purposes: this should be kept in a clean cask, in a place where smoke (which is apt to impart a bad flavour to it) cannot reach it. The management and construction of the dairy of necessity varies with the articles for which it is chiefly intended to be devoted, as Butter, Cheese, Milk; see these heads.

In the United States one of the most celebrated dairy districts is that of Western Reserve, in Ohio, peopled generally by settlers from New England. It is computed that this fine grassy country sells, annually, in Holland, the amount of a million and a half of dollars, besides large quantities of butter, and a great amount of beef and pork.

There is reason to believe that the exportation of butter and cheese from the United States to other countries will annually increase, and especially to England, where a great reduction of duties on these and other articles of the provision trade has recently taken place. From the objections made to American butter and cheese sent abroad, it seems highly desirable that more pains should be taken at home to improve their qualities, which can only be done by paying more attention to their manufacture. There is no disguising the fact, says a late writer in the Cultivator, "that immense quantities of butter find their way to market in a condition which renders it unfit for any thing but grease. Heat weather, or the voyage, renders the butter intolerably rancid. Now, butter made in Holland may be carried to any distance, and in any climate, without suffering material deterioration, and hence it is in such demand for exportation.

Vast quantities annually find their way to Great Britain for domestic consumption and otherwise, and the high prices demonstrate the estimation in which it is held. There are no finer pastures in the world than in the United States, particularly those north of the Ohio, and if proper attention and skill were given to the products of the dairy, these products might be unsurpassed. There is a considerable amount of excellent butter made in the country, but it is used for domestic consumption, and the proportion of the first rate article bears but a slight comparison with the whole. There is less difference in the cheeses of this country and the European ones than there is in the butter, and consequently less difference in the prices. But in both butter and cheese, so far as the great mass of these products are concerned, there is room for a decided improvement, and we doubt not our dairy women would content with their own interest, as well as the credit of the country, in giving more care to the production of superior articles; but to the extract.

At a public sale of American butter at Liverpool, it brought, the best sorts, 81s., seconds 72 to 74s. per cwt., duty paid, while inferior sold only at 43 to 44s. in bond, of which the parcel chiefly consisted. The quantity arrived at the London market shows the same results, the principal part being sold for greasy purposes. The American makers of butter are very far behind the Irish, English, or Dutch; from the first operation to the last, all seems to be done without system or care. The same materials would, if managed by evening hands, bring in this market 25 or 30s. more money. There is evidently no proper attention paid to the making, salting, putting down, or packing. A correspondent of one of our commercial papers says,—"The best American butter imported into England this year has sold not higher than 95s., while the best from the continent has brought 110 to 115s. per cwt.; this latter will keep for years." (London Commercial Journal for March, 1842.)

As a large portion of the United States is favoured with all the advantages requisite for dairy purposes, such as good pastures, excellent cows, fine spring-houses or facilities for making them, there is no apparent reason why good butter and cheese should not be produced in the greatest abundance. Among other instructions for improving the manufacture of butter, given in a recent volume of the Cultivator, the following merit particular attention:—

"Every thing connected with the making of butter should be perfectly sweet and clean. No smoke, dust, or disagreeable smells should ever exist in the milk-house or dairy. Everything of this kind has its effect on the cream, and leaves its taint on the butter. The milk should be skimmed, and the cream churned at the proper time and the proper temperature. The butter-milk should be promptly separated; and in salting, none but salt of the finest, purest kind is admissible. From the objection made to keeping milk or whey in the butter to putrefy, the use of bad salt has the most influence in making this article worthless. Many recommend washing butter in clear cold water to free it from the milk, and this mode is practised in some of the best butter districts of Europe or the United States. If the milk is thoroughly separated, however, the particular method is of very little consequence; and perhaps a machine for working the butter-milk out, such as has been figured in the Cultivator, or some similar contrivance, will be found as effectual as anything. But butter, if made ever so perfectly, will not keep well unless it is also packed well. Total exclusion from the air seems necessary, and when this is combined with a low temperature, butter can be kept for an indefinite period of time. It is the adventitious circumstances only that make poor butter, for, as it is a pure animal oil, if freed from those things that have a tendency to spoil it, it would keep as long and with as little trouble as tallow or lard. It is the difficulty of freeing butter from the substances connected with it, that have a constant tendency to putrefaction, that renders the packing of butter
of so much consequence to its preservation. Stone jars we have found superior to any thing else for packing butter. They are sweet, cool, impervious to air, and, from their shape, leave but a small surface to be exposed or covered with brine. The butter, whether packed in jars or firkins, must be beat solid, and the vessel, whatever its shape, should be silled at once. The difficulty attending firkins is, that all which contains more or less acid, and this, decomposing the salt, imparts an unpleasant taste and flavour to the butter in the cask. This is partly remedied by filling the firkin with strong brine, and allowing them to stand a few days before using; but the cause is never entirely removed. Experiments made in Scotland proved that the wood of the linden or basswood contained the least acid, and this is supported by the fact, that, in the Tyrolese salt-works, where water is brought to the point of saturation by percolating through bundles of twigs or fagots, those of the basswood are always preferred to any other. In this country firkins of heart-ash are preferred, and perhaps are as good as any that can be used. We have known a firkin of butter, properly headed, thrown into a well where the water was of the temperature of about 50° to 55°, and when taken out, after a submersion of a year, was as sweet as when put in. Perhaps, where circumstances admit, butter might be advantageously kept in this way in vats filled with running spring water of the proper temperature. Jars or firkins, when filled with butter, should have some pure strong brine poured on the top of the butter, and kept there for the purpose of excluding the air until the article is wanted for use. Instead of the brine some use salt, and others prefer a lined cloth last acid, and this for this purpose. But whatever is used, the top of the jar or firkin should be carefully covered with a board, or what is much better, a clean, flat stone. They should stand on flat stones, in a cool place in the cellar, and may be occasionally looked to, to see that the surface is properly secured, and the air excluded."

Some of the defects of American cheese have been referred to under the head of Cheesemaking. A very common one arises from its being too often sent to market in a very green state, frequently when but three weeks old. The best English cheeses, we are told, are not considered as ripe and marketable until two years old. "A great improvement," says Mr. Colman, "is thought by some to have been made in capping the cheeses, as it is termed; that is, as soon as they are taken from the press, covering them completely with cotton cloth, sewed over them tightly; or else drawn round the sides of the cheese and over the edges, leaving the centre partially exposed. Where the cheeses are covered entirely, the cloth itself is completely covered and saturated with the usual unguent of whey-butter and some simple and harmless colouring matter. The effect is to preserve the cheese against the attacks of flies, and to render the daily turning of the cheeses not indispensably necessary, besides preventing their spreading and cracking. It is said by some persons that the cheese does not cure so perfectly in this way as when exposed, and that the sale is not so ready. Such contradictory statements are made in this case, however, by those who have tried, and those who refuse to try it, that I cannot decide on its expediency. It impressed me favourably."

"I have much pleasure in saying that many of the Berksemi-dairies are most exemplary in respect to neatness; and in this matter present beautiful models of domestic management. There are exceptions, however, to this commendation. In some instances there is any thing but neatness. The sink and the pigsty, with all their offensive exhalations, on account of what is called convenience, which is only an apology in such cases for gross laziness, are in many too intimate proximity with the dairy-room; and there are cases—I shall not venture to say how many. Sinks are often and on the passage to the sink—where, if the pigs should perchance mistake their own apartment and go into the next door, they would never suspect their error, unless they were ordered out. Admonition, however, seems lost upon such persons. Slovenliness and sluttishness are incorrigible vices; and the fate of such persons seems, as it were, in despair of reformation, irrevocably pronounced.

"When turning slide cheese—eclairs is an admirable contrivance to save labour in the cheese-dairy. By it two men can easily turn twenty-four heavy cheeses in a minute, and are enabled to rub them without their being lifted from the shelves. The model consists of an upright frame, suspended by an axis passing through its horizontal centre; and into which slide eight pairs of shelves, the distance of which may be graduated to the size of the cheeses. The cheeses are placed alternately above and below the axis. Sinks are fixed upon the back of the frame to prevent the cheeses falling out when the frame revolves. The frame is made stationary by a pin, and when this is withdrawn, it is made to revolve half round upon its axis, which turns the cheeses. The shelves over them, and upon which the cheeses have lain the preceding day, may then be withdrawn, and left to dry till the next day, when they may be returned, the turning process repeated, and the other shelves cleaned and dried in turn. The improvement is a valuable one in large dairies. Henry Wilbur, of Richfield, Otsego Co., N. Y., is the inventor."

"The saving in labour and risk of the cheese is great, and the expense of fitting up a new room on this plan would not greatly exceed that in common use, as the room may be much smaller. One rack with six shelves, six feet long, twenty-four inches wide, set eleven inches apart, will hold eighteen cheeses weighing from 100 to 140 lbs. each, suspended by a wooden shaft two inches square, resting on two rails extending the whole length of the room, three and a half feet high, or if only a single rack, on two posts; each rack requires about four feet on the length of the rails to turn well,—and its cost will not exceed six dollars, including the materials of which it is made. On this system the cheese dries much faster, as it is turned on the dry side of the shelf every day,
DAIRY.

and has a sound and dry rind. He has one set of extra shelves, which are slipped in close above the cheesees before turned, on which shelf the cheesees lay when turned over; the others are then liberated for another rack, and so on through the room. By the aid of these six extra shelves, the cheesees in turning need not fall but a trifle, if any."

The qualities of the butter generally produced by the New England dairies are even more defective than those of the cheese. These defects are chiefly owing to causes easily remedied,—by observing perfect ventilation and cleanliness in the milk-room and all its utensils, taking the cream from the milk whilst this is still fresh, and churning soon after the skimming. The working is a matter of primary importance, and is too often but half done. The operation should be continued till every trace of the buttermilk is removed, since, if any of this be left, the butter will quickly acquire a rancid or otherwise unpleasant flavour. The salting also is of much consequence. In general too much salt is added, and that not always of the very best kind for the purpose. Much salt destroys the delicacy of fine butter. The additions of saltpetre and sugar, often made in New England dairies, is sanctioned by the practice in Scotland and other countries. See Butter. The noted richness and superior flavour of much of the Pennsylvania butter, found in the Philadelphia market, is chiefly to be ascribed to the fine sweet and clean spring-houses so common in that section of the United States, together with good old pasture fields, and great attention to working. This last, when well done, renders very little salt necessary, and hence the fine and delicate flavour of the butter can be perceived. The processes followed in the dairy districts in England are well worth the attention of persons interested in this subject. Some of these are referred to under the heads of Butter and Cheese.

Mr. Colman, in his able Reports upon the Agriculture of Massachusetts, has furnished some highly interesting details in regard to dairy affairs in the Eastern States. Treating of the interests of Berkshire county, the dairy products of many farms in which is not surpassed by any accounts of other parts of our country, or of foreign countries, which he had been able to obtain, he observes: "The dairy business has always been a great business. For a time it gave way to the raising of fine wool, when the prices of that staple were high. Since the abatement of the demand for wool, with that caprice for which mankind always have been, and there is reason to think always will be remarkable, many farmers have sacrificed their flock to room, and are now giving their exclusive attention to the dairy husbandry. These changes, in matters so important as the dairy or the sheep husbandry, involving as they do a considerable investment of capital, and many expensive fixatures, cannot be suddenly or frequently made without risk of serious loss and disadvantage."

Mr. Colman gives the following statements in relation to dairy products, expenses, net profits, &c.

A farmer residing about twenty-five miles from the Hudson, who with a stock of eighteen cows, turned his attention to making butter for the New York market, to which it was sent every week, sold in one year 2400 lbs. of butter, at 28 cts. per lb. With the refuse milk he fed seventeen spring pigs until October, when their average weight was 177 lbs. each. Half of this pork, say 88 lbs. was to be credited to the cow. Reckoning the pork at $10 per 100 lbs. (a much higher price, however, than it will now bear), the account would stand thus:

Cow, Cr. 133 lbs. of butter, at 23 cts.   $30 50
         Pork                        8 60
                                                 38 59

Cow, Dr. Wintering          $12 00
Pasturing                   5 00
Salt                        25
Interest on $25, at 10 per cent, included 2 50 19 75
Annual profits of a cow     $18 54

This calculation is made without including any extra feed for the cow, and upon the supposition that the butter and milk used by the family pays for the attendance. The profit here allowed, Mr. Colman thinks, less than that actually derived. He mentions another dairy, in which nine cows yielded 1540 lbs. of butter per annum, and 300 lbs. of cheese; and a third, where twenty cows produced—of butter, 500 lbs.; and of new milk cheese, 4000 lbs.

In the neighbourhood where these dairies are found, two acres of land are deemed sufficient for pasturing a cow or fattening a steer. Twenty head of cattle, made up of cows and three year old steers, were fattened upon thirty acres of land.

In the town or township of Otis, twenty cows gave 3600 lbs. of new-milk cheese, besides averaging 25 lbs. of butter each, for the family, which also used 600 lbs. of cheese. The credit and debtor account in this dairy may be reckoned thus:—

Cow, Cr. 260 lbs. cheese, at 8 cts. per lb.   $22 40
25 lbs. butter, at 20 cts.                   5 00
Calf                                        4 00
Pork, 26 lbs. at 6 cts.                     1 56
                                                   32 96

Cow, Dr. Wintering          $12 00
Pasturing                   5 00
Interest on cost of cow, $15, at 10 per cent, including risks 1 50
Labour and attendance        16 20 66
Balance in favour of cow    $12 34

In Sandisfield, the average yield of a cow in ordinary seasons is rated at 250 lbs. of cheese, with common keeping. By extra keeping, the quantity is increased to 350 or 400 lbs. The quantity of butter in addition to the new milk cheese, is supposed to be 40 or 50 lbs. each cow. The amount of cheese made in this township, in 1837, was estimated by competent authority, at 300,000 lbs. The population is 1493.

"Another farmer in the same neighbourhood, with a dairy of fifteen cows, states the average product of a cow, if she raises her calf, at 250 lbs.; if otherwise, 300 lbs.; and 25 lbs. butter, also, from each cow. Four hogs may be kept to twenty cows. In this way, weighing 100 lbs. in
DAIRY.

the spring, they will weigh 300 lbs. in the fall.
140 lbs. of pork is to be credited to five cows.

"The cost of wintering a cow here, is rated at $10; pasturage, $4. A good dairy woman will take charge of thirty cows, with assistance in milking and in handling cheese. Her wages will be $1 50 per week, with board.

"In Tyringham, the average yield of a cow is reckoned at—new milk cheese, 283 lbs., and butter at the same time, 57 lbs. A dairy of twenty-eight cows gave 7913 lbs. new milk cheese, and 1600 lbs. butter. A large amount of pork was fattened on this farm; but it is difficult to say what portion of it is to be credited to the dairy.

"In Sheffield, the average product of twenty-eight cows was 394 lbs. new milk cheese, and 50 lbs. of butter each.

"The product of a cow is thus stated by this excellent manager:

Cow, Cr.
400 lbs. new milk cheese at 8 cts. - - - $32.00
Calf, (killed at 3 days old) - - - 1.00
50 lbs. butter, at 10c - - - 5.00
Whey and butter-milk make 100 lbs. pork - - - 5.00

Total - - - $49.33

Supra, Dr.
Winter keeping - - - $12.00
One acre of land costing $50 will pasture the cow 2.50
Salt 25 cts., 3 lbs. of bran $3 - - - 3.25
Int. on the value of cow at $25, 10 per ct. 2.50
Labour of milking, making butter, cheese, &c. 4.60 25 25
Balance in favour of cow - - - $41.08

"The quantity of land estimated for pasturage in this case seems small. It must be small for a general rule; another farmer in the same town assured me that he kept one yoke of oxen all the season, and one horse half the season, on two and a half acres of land, which he showed me. The land had been greatly benefited by plaster.

"In New Marlboro', the yield of a cow is estimated at 300 lbs. new milk cheese; four hogs are kept to 20 cows; two tons of hay are deemed requisite for a cow; value of hay sold $10; but if the farmer can realize $6 per ton for it used on the place, he deems it better than to sell it. Eight to ten acres of land here, with the use of plaster, is deemed sufficient for the pasturage of four cows.

"In Great Barrington, nine cows produced 1900 lbs. new milk cheese, and 800 lbs. butter. In another case from eight cows were sold—of butter, 200 lbs., of new milk cheese, 1225 lbs. In another case 5 cows, through the season, and an additional cow half the season, from 1st of June to 10th Nov., produced 651 lbs. butter—and 200 lbs. new milk cheese. In this case the weekly returns were given. The same farmer says, that his cows will average one pound of butter per day through the season. He states his cow account thus:

Cow, Cr.
200 lbs. butter at 10 cts. - - - $20.00
Calf raised - - - 2.00
Buttermilk, and skim milk for pork, equal to all the care - - - $42.00

Total - - - $64.00

Supra, Dr.
Wintering, 5 tons of hay - - - $18.00
Pasturage, 25 cts. per week, 26 weeks - - - 6.50
Int. on cost of cow, $80, at 10 per ct. - - - 2.00 21.50

Profits of a cow - - - $17.00

388

"In Alford, the actual yield of a cow was as follows: Butter, 240 lbs. sold. Cheese, 100 lbs. sold, besides using what milk and butter were required by two persons. She had her own skimmed milk, but no meal or grain. She consumed, as ascertained, two tons of hay, and her pasturage was 25 cents per week."

The following estimates apply to the township of Cheshire, which is devoted almost exclusively to the dairy husbandry, and celebrated for the excellence and abundance of its produce.

"A farmer with twenty-five cows, states their average yield at 300 lbs. cheese, and 20 lbs. butter to a cow. He says likewise that 1500 lbs. pork are to be credited to his cows.

"The average cost or value of his cows is $30 each, wintering $14; pasturing 26 weeks $6 25; he raises some calves upon whey. It requires the whey of two or three cows to raise a calf. His hogs at 18 mos. average 350 lbs.; they run in a pasture and have the refuse of the dairy until about six weeks before it is intended to killed them, when they are shut up and fed with corn and meal.

"The dairy of another farmer consists of 20 cows. The year before last they yielded 400 lbs. new milk cheese; the last year 400 lbs. each, besides an ample supply of butter for the family. He calculates upon the proportion of one hog to four cows; with the above cows he made 1200 lbs. of pork, 600 lbs. of which he credits to the cows; he deems three acres necessary for the pasturage of a cow. His cows during the spring have an allowance of rye-meal and whey.

"In another case the produce of 23 cows was 12,000 lbs. new milk cheese and 500 lbs. butter.

"In another case 30 cows made 14,000 lbs. new milk cheese; and 500 lbs. butter. In this case some calves were raised; but most of them were killed at four days old. Throughout the county of Berkshire this mode of dealing with the calves is termed 'deaconing' them. What is the particular propriety of this provincialism, I am unable to determine; and whether it had its origin in any superstition among the aborigines or the first settlers of the county, I shall leave to the antiquaries to ascertain. It is a peculiarity, and prevails no where else.

"The practice, with this farmer, is to give boiled corn in case to his cows; perhaps a doz. ears to a cow per day. Where conveniently had, he gives a mess of rye-meal to each cow, at the rate of two quarts per day, for three weeks in the spring. He is anxious to let his cows go to the grass as soon as the ground is bare. He thinks cows go to the limits to suffer from excessive feeding in the barn.

The wintering of a cow requires 1.5 tons of hay $14 00
Pasturage, 20 cts. per week for 8 weeks 5 20

"In 40 days of the best of the season on this farm, 30 cows produced 4000 lbs. butter. The land required for the pasturage of a cow is considered to be three acres.

"From thirty cows, an average of 425 lbs. of cheese has been produced to each cow, and ten lbs. of butter; or 300 the whole.
DAIRY.

"On one farm, where 18 cows were kept, 11,385 lbs. new milk cheese were made in a season, which gives the extraordinary average of 632 lbs. to a cow. 200 lbs. of butter were made the same season from the same cows. One of these cows produced 1000 lbs. new milk cheese.

"During the first part of the season, for two months, two quarts of rye-meal were given to each cow. Half of this quantity of meal was given them for one month during the last of the season; and the greater part of the time they had their whey. 1000 lbs. pork were made on the farm; and half of this was credited to the cows.

"The same individual, when on another farm in South Adams, with 21 cows, made 626 lbs. new milk cheese to a cow, in a season. 1700 lbs. of pork were raised in connection with the dairy. Half the pork was considered as due to the cows.

"The process of making cheese began the 25th April, and ended the 1st December. As soon as the cows calved, the cows received 3 qts. of meal per day each—principally rye, with some Indian; and each had some whey, though not half what was yielded was given to them. Three or four of the cows received meal all the summer. He commenced feeding again with meal on the 25th July, and continued to give them two quarts of meal until the 25th August. On the 25th August, he began feeding the cows with corn-stalks until 10th September. Then the cows had the after feed of the fields; and from the 1st October, these cows had half a load of pumpkins per day. In November, fed every cow fully with meal; two and three quarts per day until 1st December. After that, the cows had nothing but hay until spring. From the same cows, at the same time, butter enough was made, and milk enough used, for a family of six persons. The cheese sold in New York for $10 dollars per 100 lbs.

"These products are certainly remarkable, and show what may be done by attention, skill, and good treatment of the animals under our care. The pasturage in Cheshire is of an excellent description. The soil is generally of a rich gravelly loam resting upon limestone, and abounding in vegetable mould. It is likewise sensitive to the application of plaster, which is very commonly used."

The same excellent authority who has furnished the foregoing details, enables us to present the following views of farmers in those sections of Massachusetts most celebrated for dairy products in regard to dairy stock.

"The farmers are unanimous in their preference of the common native stock of the country, in which the Devon blood predominates, to any foreign stock with which they are acquainted. They are in general as decided in their preference of small, over large-sized cows. They are not, however, raisers of stock; and buy their cows wherever they can find them, according to their best judgment. The remarkable produce, if so it be considered, is to be attributed to extraordinary good management and keeping; and on this account, deserves the more attention, as showing what may be done.

DAIRY.

"The dairy stock in England which seems to have the preference over all others, is the Ayrshire. The origin of this stock is not well ascertained; but though it has some of the qualities of the improved Durham, is a race distinct from that. Great pains have been taken and great expenses incurred, in order to introduce this fine Ayrshire race of cows into our state, by the Massachusetts Agricultural Society, and by an intelligent and public-spirited friend to agricultural improvement in Waterstown. I regret that I am not able to obtain such returns as would enable me to speak confidently of the merits or defects of this stock, so far as these cases go;—but I am safe in saying, that some slight disappointment has been experienced. It is probable from the celebrity which they had obtained abroad, too much was expected from them here. Extravagant statements have been made respecting their produce in Scotland. One of the advocates for this stock, and a man upon whose authority great reliance is placed, has undertaken to calculate precisely the number of quarts of milk given, and the number of pounds of cheese made from what is stated to be in money the average produce of an Ayrshire cow. This is now practically reaching the result. Entire reliance cannot be placed upon it. This, another distinguished Scotch farmer and dairymen admits; and says that 'those statements are far too high and not well founded.'

"He refers to a farmer, on whose exactness he entirely relies; whom he pronounces a man of superior intelligence and accuracy; and who has devoted himself to dairy husbandry; and, further, whose stock were particularly select and 'who had every inducement to keep them in the highest condition requisite for giving the largest product in milk.' The farmer referred to, states, that at the best of the season the average milk from each cow is 9 Scots pints (41 gallons), and in a year, 1300 Scots pints or 650 gallons. A Scots pint is two quarts. Now, allowing these cows to be in milk 320 days, the average yield of a cow would be 8½ of a quart per day. But if we understand this to be wine measure, which is the usual standard of measurement in England, and compare it with our customary admeasurement of milk in Massachusetts, which is always beer measure, we must deduct one-fifth; and then the average product of an Ayrshire cow, compared with ours, is 6½ quarts per day for 320 days. Such a yield is often surpassed by cows of our native stock. I have before me the case of a cow of native stock among us, who, in 268 days, yielded 2923 beer quarts of milk; and of another, that produced 3975 beer quarts of milk in ten months. I can produce, within my own knowledge, a list of nearly fifty cows of native stock, almost as productive as these. I do not mean to undervalue the imported stock. Far from it. I deem the introduction of the Ayrshire stock and the improved Durham short-horn, a great benefaction to the country. Their tendency to fatten, their early maturity, their beautiful proportions, highly commend them to our good will and our interests. As 2 x 2 389
yet, we have not had, by any means, a sufficiently fair trial of their dairy properties so as to determine fully, either for or against them; and it has been found here, in repeated instances, as it has proved abroad, that a cow, from a cross of an improved Durham, with the Devon, has given a valuable animal for the dairy, but the great advantages which is to result from the introduction of this improved and beautiful stock, is this: to give our farmers a knowledge of what can be done by skill, intelligence, care, selection, and perseverance in the art of breeding animals for any purpose; in obviating defects of form, constitution, and habit; and in perpetuating and transmitting excellent and desirable properties. In the Ayrshire stock, and in the improved short-horns, the most shrewd and persevering effort and care has been exerted, and the highest practical skill and philosophy have been taxed to carry this race to so great a degree of perfection as any thing of the kind can be; and the success has been decisive and wonderful. Excepting in one instance, to which I shall hereafter refer at large, perhaps there cannot be found in the whole of New England, a single instance of any enlightened, determined, and systematic attempt to form a race of animals of particular and desirable properties. It is most important that this should be attempted in different parts of our country, with what are called our native stock, which have become, in various ways, so crossed and mixed up, that there is in truth no particular race among them. A large portion of them are as ungainly, unhairy, and unproductive as can well be represented or imagined. Yet there are among them so many extraordinary animals,—extraordinary for the size, strength, and beauty in milk, butter, and cheese,—that a few years of careful and intelligent selection from the materials already to our hand, and a strict observance of those philosophical principles of breeding which are well ascertained and understood, would undoubtedly give us a breed of animals, a stock or race of animals, greatly superior to that which now exists among us. This has been attempted in one instance by a highly intelligent breeder; and he is not able to show the characteristics of animals of an extraordinary character for the creamy or butyricous quality of their milk as has ever been known. Two quarts of what is called the strippings, the last part drawn off of the milk of one of these cows, having repeatedly produced one pound of butter; and the cream, as it came from the pans, as I have seen myself, becoming by churning converted into butter of the finest description in less than one minute by the watch; and this process repeated at pleasure.

"Let us now compare the amount of cheese made by the English dairies, with some in this county of which I have given here an account.

"An Ayrshire cow, it is said by the English authorities, will yield 257 lbs. of butter per annum, or about 5 lbs. per week, all the year round, besides raising the calf; or of new milk cheese, about 514 lbs. These returns are certainly large; but they rest upon a calculation of the quantity of milk which the cow is supposed to yield, rather than upon any account of an actual yield. None at least is given. This, therefore, is not so satisfactory as it would be, if it were a precisely ascertained result. One of the best authorities says, that in England, a well-fed cow of a good breed will produce, upon an average, 180 lbs. of butter in the season. The common calculation is indeed 150 lbs.; but this is made upon mixed stock, which affords no certain data. In the Epping district, where there is an indiscriminate mixture of Devon, Suffolk, Leicester, Holderness, and Scotch, the calculation, in a well-managed dairy amounts to 212 lbs.; that is, 6 lbs. per week during 36 weeks, and 4 lbs. per week, during 14 weeks. The average product of cheese in the best cases of the whole milk and cream are used, cannot be estimated at more than 4 cwt.—that is, 448 lbs. On deep grazing soils, that carry a heavy stock, a well-managed cow is reckoned to make from 360 lbs. to 600 lbs. In Somersetshire, the average is 44 cwt., or 540 lbs.; in Essex not so high, and in the midland counties something more than 3 cwt. It will be seen, in looking back upon the dairy returns in some parts of this country, that they are inferior to these, not frequently passing beyond 200 or 300 lbs. of the new milk cheese. On the other hand, the returns of some of the dairies in Cheshire show an actual amount of annual produce of more than 500 lbs. to a cow, and in some cases 627 and 632 lbs. It may be said that this is owing to the fine pasturage which is to be found in Cheshire and its vicinity; to the particular care which is taken of the cows; and the system of high feeding adopted. But it shows conclusively that the cows are capacious, and being brought to this productive yield; and the feed and management are matters which can be adopted anywhere.

"A farmer in Sandisfield has a dairy of 24 cows; and they produce a cheese per day, weighing about 100 lbs. Supposing that it requires a gallon of milk to produce one pound of cheese, this would give 400 quarts of milk per day, or at the rate of 194 of a quart per cow. The cows are of the native breed, and most of them raised by himself. His average product of new milk cheese to a cow in a season, is between 500 and 600 lbs. Last year the actual yield was 598 lbs. to a cow. Of his 24 cows last year, two were heifers of two years old, just come in. Four years since he was the owner of a cow, whose milk in the best season amounted by actual weight to 70 lbs. per day. During the time of her greatest yield, she was fed with four pails of cheese whey, and some rye-meal. She was of native stock. This farmer has a heifer from her, which gives, as he supposes, 60 lbs. of milk per day. He gives an opinion, which from his successful experience certainly deserves attention; that heifers which 'come in' with their first calf at two years old, do better than when their coming in is delayed until three years old. Their milking properties are in this way improved. Probably he is right in this matter; but the general experience of the best farmers recommends that, if a heifer
DAIRY.

comes in at two years old, she should not be allowed to have another calf, under at least eighteen months from this time."

In regard to the improvement in cot cattle milk. Though a substantial improvement is being made in New England, Mr. Colman furnishes the following results, obtained at Ten Hills Stock Farm, near Boston, under the entering efforts of Samuel Jaques, than whom, he thinks, no man, perhaps, in New England or the whole country, has more practical skill or better judgment in relation to this kind of live-stock, his experience having been long, and marked by critical observation. The following extract contains Mr. Jaques’s own account of his enterprise and success, as communicated to Mr. Colman:

"It has," Mr. J. observes, "been my object to effect such an improvement in milch cows as should produce the greatest quantity of rich milk, affording the largest quantity of butter. There is a greater difference in pecuniary profit between a good or a poor cow than among any other domestic animals. In some yards there may be found those which will not produce more than three pounds per week, and the stall which would make nine, and all on the same keep. As we sometimes hear of cows which have produced seventeen pounds of butter per week, and even more, it occurred to me to inquire why a breed or race could not be formed with the same valuable properties. This I have attempted, and have carried it to the third generation; and I am confident of success. I have a cow whose milk has produced nine pounds of the best butter in three days, and this on grass feed only. This I call my Cream-Pot breed. I have bred my cream-pots with red or mahogany-coloured hair, yellow noses, with mahogany-coloured teats, yellow skin, silky and elastic to the touch. I have obtained the breed by the cross of a Durham short-horned bull on a selected native cow with certain extraordinary points and properties, anxious to retain as much of the form of the Durham as to assure capacious udders, and with the valuable property of affording rich milk. As to the short-horns, I have not found them producing so rich milk nor making so much yellow butter as I could wish. The Durham race are round and straight in the barrel, full in the twist, and inclining to be thick in the thigh. I have wished for some improvement in the form of the bag. But I would premise, that whatever I may say in respect to breeding animals, I only desire to express my own private notions, without a wish to dictate to any one from the experience I have had, which I am sensible is very limited. Generally, cows which I have examined, giving the largest amount of the richest milk, have had capacious bags, full behind, extending far up into the twist, and also well formed; hanging moderately deep when full in milk, and after the milk is drawn, quite the reverse; for I would avoid a fleshy bag. My cream-pot breed are full in the body, drop deep in the flank, are not quite so straight in the belly, nor as full in the twist, for as thick in the thigh; but in other respects I wish them to approach the Durham as near as may be. My cream-pot breed excel particularly in afford-
and consistency are remarkable; and in company with several gentlemen of the legislature, I saw a portion of it converted into butter with a spoon in one minute. The colour of Mr. Jaques's stock is a deep red, a favourite colour in New England. They are well formed, and thifty upon common feed; and, if they continue to display the extraordinary properties by which they are now distinguished, they promise to prove themselves, for dairy purposes, the most valuable race of animals ever known among us, and as remarkable as any of which we have any information. They have now reached the third generation, and maintain their high character.

"From six cows taken promiscuously in a dairy of improved short-horn stock, in England, with a view to test the quality of the milk, it was found that they gave in the following proportion of butter to one quart of milk:

No. 1, 3 oz. 6 dwt. No. 4, 1 oz. 10 dwt.
2, 1 " 6 " 5, 1 " 14 "
3, 1 " 12 " 6, 1 " 6 "

"These measures, it will be perceived, are given in troy weight, of which it requires 175 lbs. to make 144 lbs. avoirdupois. It is not stated whether the quart was wine or beer measure, and it is therefore difficult to adjust the proportions. A variety of circumstances, likewise, would affect, in some degree, the result; as, whether the milk was taken at the beginning or the last part of the milking; and how long the cows had been in milk from the time of calving; and what was the kind of feed given them at the time of the experiment. Still, I have quoted the result, as, under any circumstances, showing by comparison the extraordinary product of the cream-pot breed."

Mr. Colman has added to his report of the dairy produce of the county of Cheshire, a table showing the number of cows kept on 45 farms in 1838, with their produce, the amount sold, and prices obtained. The whole number of cows was 913; the amount of new-milk cheese sold, 300,000 lbs.; skim-milk cheese, 11,050; cheese used, 7,500 lbs.; butter sold, 19,050 lbs. The average price for the new-milk cheese was 7½ cts.; of skim-milk cheese, 3 cts., and of butter, 17 cts. per pound.

In the dairy establishments about Boston, good hay, and corn-fodder are the general feed, with sometimes carrots, rutabaga, and mangel-wurtzel. The rutabaga, and all the turnip family, are apt to impart a turnip taste to the milk, which is very generally disliked. Mr. Colman was informed by a very careful milkman that no objection of this sort is found against rutabaga, if they be given to the cows directly after, and not just before being milked. Before the next milking comes, the disagreeable odour is entirely got rid of. The best milkmen prefer good clover hay for cows in milk to any other. "Potatoes and mangel-wurtzel," says Mr. Colman, "increase the quantity without improving the quality of the milk. Carrots, parsnips, and sugar-beets improve the quality.—A milk farm, well situated and with a good custom, is a profitable husbandry where the milk brings 5 cents in summer and 6½ cents in winter. A good deal of milk is sold by the farmers to the milkmen for 3 cents per quart, of the profits of which management to the farmer I have strong doubts. If we suppose that it requires 10 quarts of milk to make one pound of butter, this at 3 cents per quart would be 30 cents. Suppose the milk to be made into butter, there is a pound of butter worth 25 cents, and, if of superior quality, 33; there are the skim-milk and butter-milk remaining, worth certainly for young pigs 1½ per cent per quart—say 8 quarts, 13 cents; and there is the manure made by the swine kept, which is of considerable value. "The amount of milk furnished by a herd of cows through the year is very differently estimated by different persons. Rare individual cows may be occasionally met with, giving ten, and perhaps, in some remarkable case, even eleven quarts of milk per day through the year—that is, 365 times 11 quarts, or more than 4000 quarts per annum; but such cases are very few in number. In Curwen's dairy of 28 cows, kept and fed with great care for 220 days, the average was eight wine quarts per day, or a little more than six beer quarts. In the Harleian dairy, where a hundred cows were kept, it is said that twelve wine quarts were about the daily average; but the statement, in the form in which it is made, is very imperfect and doubtful. Twelve wine quarts would exceed the beer quarts. Nothing could surpass the pains used in the selection of these cows, the care taken of them, and the abundance with which they were fed. If the statement were positive, I should regard it differently; but as it seems to be rather matter of conjecture than of proof, I place little dependence upon it. In a private letter to a respected friend from the celebrated Fellenberg, it is stated that, at that institution, the cows, which are considered amongst the best milk cows in the world, average through the year about six quarts per day. But here again we are left at a loss to know, whether the year includes only the season while they are in milk, or 365 days. These are foreign statements. I wish I had those from among ourselves, on which entire reliance can be placed. Men in these cases are so in the habit of dealing in conjecture instead of facts, that it is exceedingly difficult to arrive at the truth. I have been so often deceived in these matters that I place little confidence in anything which is not matter of actual measurement and positive verification. The most intelligent and careful milkmen whom I have consulted are of opinion, that their cows average about six quarts per day for 365 days, and go dry in that time from two to three months. A very careful milkman, who may be entirely relied on, from 20 cows produced 11,131½ gallons of milk in a year. This was at the rate of 6½ quarts per day for 360 days, or 7½ quarts per day for 300 days. These cows were native stock, extremely well selected and well fed. Successive trials on this same farm give about the same result. "On a milk establishment in Medford, under excellent management for many years, with twenty cows in summer and more than thirty in winter, the average product for 365 days is from five to six quarts to a cow per day. The
cows are fed in winter upon clover hay, an allowance of a peck and a half each of succulent vegetables, and some Indian or oil-meal cake. The summer feed is not stated, but great advantage has been derived from green Indian corn fodder. Oil-meal cake is not considered of equal advantage with Indian. It is deemed too dear, as more than $25 per ton.

Carrots are referred to all other vegetables when the quality of the milk and the condition of the animal are regarded. Since the use of the most powerful hydrostatic presses in extracting the oil from the flax-seed, the cake is by no means so valuable as formerly, and the price should be proportional.

"In the case of a milk establishment in the vicinity of Salem, on an average of thirty-five cows in milk; the product in one year was 17,171 gallons of milk, beer measure; in another year, it was 17,530 gallons. In the first case it would be about 5§ quarts to a cow; in the latter, 5½ to a cow per day through the year."

Several enterprising individuals have imported some of the very finest bulls and cows, of the Ayrshire breed, generally reputed the most celebrated dairy stock in England. In regard to the qualities of these and their progeny, Mr. Colman remarks that they are said to yield large quantities of milk and produce large amounts of butter and cheese; besides keeping themselves in good condition, and being easily made ready for the butterer. The cows are eminently beautiful. In size, however, and symmetry, they are decidedly inferior to the improved Durham short-horns; but there is good reason to think them a harder race of animals.

Of the improved Durham short-horn race, we have, Mr. Colman remarks, had some of the best animals ever brought into the United States, and their blood has been considerably diffused throughout the country. In point of size according to their age, in respect to symmetry and perfection of form, these animals are, in my opinion, not surpassed, indeed not equalled by any others. "The Herefords," he says, "are extremely beautiful; in neatness and fineness of form perhaps superior to the improved short-horns; the Devons likewise, though considerably smaller in size, yield, in compactness of shape, in quickness of movement and muscular strength, and in softness of hair and beauty of colouring, to no other race known among us. They are the prevalent race of our country; and in an extraordinary instance, when I had the singular pleasure of seeing three hundred yoke of these cattle—that is, all more or less of this breed—in one team, in Connecticut, I could not resist the conclusion that a finer team, of the same number of cattle, could not be found in the whole country. Yet I am ready to admit that I have seen some few yokes of oxen of mixed blood, of the improved Durham, as fine in appearance, and in reputation as good animals for work, as any that I have met with; and some individual animals of the improved Durham short-horns, both pure and half-blood, bulls, oxen, and cows, when all points have been considered, have surpassed any thing which I have seen. They have approached as nearly to what I imagine the perfection of form in this race of animals as is to be looked for. With good keeping, they come early to maturity, and attain a large weight. The butchers, however, whom I have consulted, give it as their opinion that they do not tallow so well, in proportion to their size, as our own smaller cattle. In my observation, no animals degenerate sooner under neglect and poor keeping; and they require extraordinary feed and the most careful attendance to keep up their character and condition."

"So much sensibility exists in reference to this subject, the dairy properties of the improved short-horns, and so much of private interest and speculation is now mingling itself in the judgments which are formerly given in the case, that, if it is not difficult to speak with calmness and sobriety, it may be unreasonable to expect to be heard with candour and impartiality."

With this judicious remark, Mr. Colman proceeds to give well authenticated reports made of the milking exploits of the short-horns and their crosses, followed by the most celebrated performances of native cows, in yielding milk, butter, and cheese.

From the numerous examples recorded of superior dairy qualities exhibited in native cows, we cannot omit the following:

"The Oakes cow, in Danvers, Mass., produced in 1813, 180 lbs. of butter; in 1814, 300 lbs.; in 1815, over 400 lbs.; in 1816, 484 lbs. During this time, one quart of the milk was reserved daily for family use, and she suckled four calves for four weeks each, in the course of those years. She produced in one week 194 lbs. of butter, and an average of more than 16 lbs. of butter per week, for three months in succession. The largest amount of milk given by her in one day, was 44½ lbs. She was allowed 30 to 35 bushels of Indian meal per year, and all her own skimmed milk and most of the buttermilk. At one time, the owner gave her potatoes, which increased her milk, but not her butter. In the autumn, he gave her about six bushels of carrots. A cow owned by Thomas Hodges, in North Adams, produced last year 425 lbs. of butter; 400 lbs. of this amount were made in nine months. Her feed consisted of one quart of rye-meal, and half a peck of potatoes per day; and very good pasturing.

"Cow of Ralph Haskins, Dorchester, Mass., 1827. Eighteen quarts per day—average 14 to 15 quarts. Before grass feed in April, the cream of two days made 2½ lbs. butter, and was made from 2½ quarts of cream. Two or three minutes in churning. This was the mother of Mr. Jacques's famous Cream-pot breed.

"Cow of H. G. Newcomb, Greenfield, Mass., 1830, from March 27th to May 25th, made 100 lbs. of butter, and reserved 160 quarts milk. In 14 days, made 29½ lbs. butter.

"Cow of Shelburne, Vt., has yielded 26 quarts, beer measure, in a day; and at two milkings in 24 hours, produced 3 lbs. 14 oz. of butter. This cow was raised in Vermont. Some of her sons, from her great product, call her English.
but the admixture of blood is very small if any; and if any, it is not known, whether Durham, or Ayrshire, or what. There is nothing but her colour, which indicates any difference from our best formed native stock. She has some progeny by an Ayrshire bull, which are very promising.

"Cow of S. Henshaw, Springfield. 17§ lbs. of butter per week, and in one case, 21 lbs. of excellent butter. In § days, that is 4 days and one milking, she produced a 14 lbs. 15 oz. of butter, at the rate of 22§ lbs. per week.

Cow of O. Morris, Springfield. "The summer after she was seven years old, the quantity of butter made from her between the first day of April and the first of September, five months, was 206 lbs. During the time, we used milk and cream in the family freely. Some weeks we have made 14 lbs., exclusive of milk and cream used for family purposes. I have often weighed her milk in the month of June, and she has frequently yielded 31 lbs. at one milking at night. We have been particular to have her milked in the summer at five o'clock in the morning and at seven o'clock in the evening, and always by the same person. I think much of regularity in the times of milking; and that one person only should be permitted to milk the same cow the same season. My cow has always had a good milker, and her milk has been rapidly drawn. Her food in the winter is good hay, and in addition thereto from 5 to 4 quarts of rye-bran at noon. I feed and give her water three times each day. In the summer, besides the pasture, she has 4 quarts of rye-bran at night. From the experience I have had with this cow, I feel quite sure that many cows which have been considered as quite ordinary, might, by kind and regular treatment, good and regular feeding and proper care in milking, have ranked among the first-rate."

For their dairy products these examples of native breed are certainly admirable. They do not, however, equal those reported of many Durhams in our country, among which may be mentioned the Belina of Mr. John Hare Powell of Pennsylvania, an improved Durham, which yielded repeatedly 26 quarts of milk in 24 hours, and produced in three days 8 lbs. 13 oz. of butter; or at the rate of 20¼ lbs. per week; the feed consisted of slop composed of Indian meal, with clover and orchard-grass. One quart of the cream produced 1 lb. 5¼ oz. of butter. In one instance two minutes, and in another only three seconds were required to convert the cream into butter.

The celebrated Blossom, also an improved Durham short-horn cow, owned by Mr. Canby, in Delaware, gave 253½ quarts per week, being an average of 36 quarts per day; from which were made 17½ lbs. of well-worked butter.

The famous Durham cow Dainty Maid, belonging to Mr. James Gowen of Germantown near Philadelphia, yielded 33¼ quarts of milk per day.

Neither do any of these distinguished milch cows equal in dairy qualities the celebrated Cramp cow, owned in Lewes, England, which still bears the palm both abroad and at home. She was of the Sussex breed, and came of a celebrated stock. Her performances recorded were as follows:

"From the first day of May, 1805, the day she calved, to the second day of April, 1806, a space of forty-eight weeks and one day, her milk produced 540 lbs. of butter. The largest amount made in any one week, was 15 lbs. From May to June, she gave 20 quarts per day. From 20th June, to 10th September, 18§ quarts. In forty-seven weeks, she produced 450 lbs. of butter. The largest amount per week was 12 lbs. The quantity of milk for the time was 4,137 quarts. During this year, she was sick and under a farrier's care three weeks after calving. She went dry seventeen days only.

"In the third year, from the 6th of April, 1807, the day she calved, to the 4th April, 1808, fifty-three weeks and three days, she produced 675 lbs. of butter. The largest amount made in a week was 18 lbs. The quantity of milk given in that time was 5,782 quarts. In the fourth year, from the 22d April, 1808, the day she calved, to the 13th February, 1809, forty-two weeks and three days, she produced 466 lbs. of butter. The quantity of milk given in the time was 4,319 quarts. In the fifth year, from April 3d, 1809, to May 8th, fifty-seven weeks, her produce of butter was 594 lbs. The amount of milk given in the time was 5,369 quarts. The largest quantity of butter in any week was 17 lbs. This is the most extraordinary cow of which we have any record. Though it has been presented to the public before, yet the account may not be accessible to all; and I deem it useful to state the mode of her treatment.

"In the summer season, she was fed on clover, lucerne, rye-grass and carrots, three or four times a day; and at noon, about four gallons of grains and two of bran, mixed together, always observing to give her no more feed than she eats up clean. In the winter season, she was fed with hay, grains, and bran, mixed as before stated, feeding her often, viz., five or six times a day, as was seen proper, and giving her food when milking; keeping the manger clean, where she is fed with grains; not to let it get sour; wash herudder at milking three times with cold water, winter and summer; never tie up; lies in or out the barn as she likes; particularly careful to milk her regularly and clean. Milch cows are often spoiled for want of patience at the latter end of milking them."

With regard to the merits of the Durham breed, about which such a variety of opinions have been entertained, Mr. Colman expresses himself as follows:

"The beauty of the improved Durham short-horns and their perfection of form are admirable. They come with good keeping early to maturity. They have a tendency to keep themselves in good condition; and, with extraordinary feeding and care, they arrive at a large size, and some individuals, all points considered, have surpassed any thing within my knowledge. The Claremont ox, a half-blood Dur-
DAIRY.

ham, whose pedigree is not known, which was sent from this country to England for exhibition three years since, was pronounced by competent judges the finest animal of the kind ever seen there. His live weight was reported as not far from 3700 lbs. The Greenland ox was nearly as heavy, and singularly beautiful. A native ox exhibited in Boston, in 1840, did not differ much from these in size, fulness, and weight; but compared with them in appearance, he was misshapen and deformed. The Durham cows, in general, especially the selected ones, which have been imported on account of these qualities, are large milkers; but their milk seems generally inferior as to richness or butyraseous properties. The milking properties of Mr. Whitney's stock, at New Haven, are very remarkable. The Durham cows are large animals, and should be expected to secrete largely of milk; but many of them, however, are inferior as milkers; and, upon as calm and impartial a view of the subject as I can take, from my own personal observation, I cannot pronounce them, as a race, distinguished and preferable to all others for their dairy qualities. I have come to this conclusion with the strong prejudice from the favour; and as I measure my words in this case, I wish to be judged only by what I say. Whenever a short-horn cow proves an inferior milker, the enthusiastic advocates of the race are pleased to tell us that it is because she has no pedigree, and is not a hard-book animal; but admitting that her genealogy is somewhat mixed, it is singular that the virtues of the blood should not show themselves to a degree, and that the impurity or defect should always predominate. It is certain, however, that many milkers now have in every respect excelled many of the pure breeds."

Such are the respective merits of the short-horned and common breeds for dairy purposes, according to the experience of one who has had extensive opportunities for observation, and who is to be regarded as a candid and impartial witness. We think, however, that the most just view of the subject is presented in the following extracts from the Edinburgh Quarterly Journal of Agriculture, and we are pleased to find this opinion sustained by no less an authority than the late Judge Buel, who has endorsed the sensible views of the European writer, by imbodying them in his Farmer's Instructor.

"It has been frequently asserted that short-horned cows are bad milkers; indeed, that no kind of cattle are so deficient in milk. Those who say so do not know the still greater deficiencies of the Herefords, a species of cattle quite unknown in Scotland. The highest bred stocks of the Messrs. Collins, Mr. Mason, and Mr. Robertson, yielded little milk. Indeed, Mr. Robertson's could not supply milk sufficient for their own calves, at least not in the quantity which it was desired by him they should receive. Cows were kept for the purpose of supplying the deficiency of milk of the high-bred cows. But this deficiency of milk did not altogether proceed from the circumstance of the cows being of the short-horned breed; because those eminent breeders, devoted their whole attention to the development of flesh, and not at all to the development of milk. Had the flesh been neglected as much as the milk, and the property of giving milk as much cherished as the development of flesh, their short-horned cows would have been deep milkers. As it is, the generality of short-horned cows are not bad milkers. Indeed, it is not to be doubted that where the general secreting powers of the animal system have been increased, as it has been in that of the short-horns, the power of secreting milk will be increased with the power of secreting flesh and fat; all that seems requisite is to encourage the power of that secretion which for the time is most wanted. I have no doubt that it is completely within the power of the breeders of short-horns to make them good milkers. It would be to desire an impossibility, to desire the full development of flesh, fat, and milk at the same time; but there is no absurdity in desiring a large secretion of flesh and fat at one time, and a large secretion of milk at another, from the same cow. Accordingly, this is the very character which has been acquired by short-horned cows. They will yield from six to sixteen quarts a day through the year, and the constant milkers that they seldom remain dry above six weeks or two months before the time of calving.

"But the practice of the owners of public dairies in towns, were there no other proof, would prove the milking powers of short-horn cows. They prefer them as the greatest and most steady milkers; and it is now difficult to see cows of any breeds but short-horns or crosses with them in these dairies. In London, in the power of the breeders of short-horns, may be seen at the public dairies. They are bought by the milkmen whenever they come of age, that is, five or six years old. They give milk till they attain the age of eight or nine, and are then fed off fat for the butcher. These cows can be fed off fat. This property, and that of milking, prove clearly that short-horns possess both in a remarkable degree. They do not, it is true, possess both in an eminent degree at the same time; but they exhibit this property separately when it is desired. They thus give a return in flesh for part of their original high price, while they remunerate their owners in the mean time with an abundance of milk for their food."

Dairies in Holland.—Holland has long been celebrated for its fine dairies, and the Highland Society of Scotland, considering that the Scotch dairies might derive some advantages from an acquaintance with the management of those of Holland, offered a premium for the best report upon that subject, founded upon personal observation. The premium was in 1833 awarded to John Mitchell, whose report, filled with interesting facts and details, is published in the Transactions of the Highland Society for that year. In the quotation formerly made from the London Commercial Journal, the superior qualities and higher market value of Dutch butter were referred to. Some idea of the dairy produce of Holland may be gained by considering, that in addition to the home consumption of a populous country, and the
vast quantities sent to other parts of Europe, to the West and East Indies, and other parts of the world, England imported in 1830 no less than 116,233 cwt. of Dutch butter, and 167,913 cwt. of Dutch cheese.

The pastures in Holland, as is generally known, have been reclaimed from the ocean, the waters of which are kept off by artificial embankments. The lands, of course, lie very low and flat, and as the water in the numerous canals is always near the top, the soil must be moist. The ground is seldom broken up with the plough, which is kept in good condition by top dressings, consisting chiefly of the solid, and especially the liquid manures collected in the cow-houses, mixed with the scrapings of the small canals. The first year after such dressing the land is generally mown for hay.

The Hollanders make careful selections of their cows for the dairy, the price of good ones being usually from $40 to $45. They are generally fattened and turned out. There is a generally held opinion that cattle are so fattened, and bears at four or five. The cows are turned to pasture in March or April, and are at first covered with a very thick cloth of tow, covering the upper half of the body from the shoulders to the tail, to prevent diseases from cold. They are pastured about thirty weeks. Hay is their common food in winter, though rape-cake and brewer’s grains are sometimes added. The byers or cow-houses are generally lofty, airy, paved with large square bricks, and kept perfectly clean. The roof is about ten feet high. There are no racks or mangers, but the food placed in gutters, always clean, near their heads. Gutters in the rear serve to carry off the urine and dung, and these gutters are also kept clean.

Process of manufacture.—The cows are always milked by the men, and the butter and cheese made by the women, generally of the family. Ninety cows are managed by nine men and two women. There is generally here a man required to ten cows; while two women are considered enough for any dairy. The farmer reckons that he can make 100 gilders, about $40, per annum, by each cow.

Butter.—There are three distinct kinds of butter made in Holland; grass butter, made when the cows are at grass; whey butter, from the whey of sweet milk cheese; and hay butter, made in winter.

Grass butter.—The cows being carefully milked to the last drop, the pitchers containing the milk are put into the koelbak. When the cream has been gathered and is soured, and if there is a sufficient quantity from the number of cows, they churn every twenty-four hours, the churn being half filled with the soured cream. A little boiled warm water is added in winter, to give the whole the proper degree of heat, and in very warm weather the milk is first cooled in the koelbak or cooler. In small dairies the milk is sometimes churned, when soured, without separating the cream. The butter, immediately after being taken out of the churn, is put into a shallow tub, called a vloot, and carefully washed with pure cold water. It is then worked with a slight sprinkling of fine salt, whether for immediate use or the barrel. When the cows have been three weeks at grass, the butter is delicious, is made in fanciful shapes of lambs, stuck with the flowers of the polyanthus, pyramids, &c., and sells as high as 44 stivers, 60 to 70 cents, the 17 oz. or Dutch pound. If intended for barrelling, the butter is worked up twice or thrice a day, with soft, fine salt, for three days, in a flat tub, there being about two pounds of this salt allowed for fourteen pounds of butter; the butter is then hard packed by thin layers into easks, which easks are previously carefully seasoned and cleaned. They are always of oak, well smoothed inside. Before being used, they are allowed to stand three or four days, filled with sour whey, and thereafter carefully washed out and dried. Each cow, after being some time at grass, yields about one Dutch pound (17½ oz.) of butter per day.

We beg our dairy-women,” says Judge Buel, “to mark two points in the preceding process. 1. No salt is used but what is incorporated with and dissolved in the butter, and which is necessary to give it flavour; and, 2. The butter intended for keeping is worked from six to ten times, to incorporate the salt, and to separate from it every particle of liquid, which, if left in it, would induce rancidity.

Hay butter undergoes a like process.

Whey butter.—The whey is allowed to stand three days or a week, after being separated from the curd, when the cream is skimmed off, or the whey itself put into the churn, and the butter is formed in about an hour. By this process, in winter, one pound of butter is obtained from each cow in a week, and in summer one pound and a half. The relative prices are generally, grass butter $3 stivers, hay butter 7, and whey butter 6.

Cheese.—There are four kinds of staple cheese made in Holland; the Edam and Gouda, both made from skimmed milk; and two kinds, Ketner cheese, made from milk once or twice skimmed.

Edam cheese.—The process of manufacture of the Edam cheese is as follows:

“The milk being yearned as soon as taken from the cow, when coagulated, the hand or a wooden bowl is passed gently two or three times through the curds, which are then allowed to stand a few minutes. The bowl or finger is again passed through them, and they stand a few minutes. The whey is then taken off with the wooden bowl, and the curd is then put into a wooden form (of the proper size and shape of the cheese to be made). This form is cut out of the solid wood by a turner, and has one hole in the bottom. If the cheese is of the small size (about 4 lbs.), it remains in this form about ten or twelve days; if the large sized, it remains about fourteen days. It is turned daily, the upper part during this time being kept sprinkled with about two ounces of purified salt of the large crystals. It is then removed into a second box or form of the same size, with four holes in the bottom, and put under a press of about 50 lbs. weight, which it remains from two to three hours if of the small size, and from four to six if of the large size. It is then taken out, and put on a dry, airy shelf in the cheese apartment, and daily turned over for about four
DAIRY.

weeks, when they are generally fit to be taken to market.

"Alkmaar, in North Holland, is the great market for Edam cheese. It is not uncommon to see 500 farmers at the market, and 470,000 cheeses for sale on one day. The price there averages about 30s. per cwt. ($6 66). (Cultivator.)"

"Gouda cheese.—This kind of cheese is also made from the milk immediately on its being taken from the cow. After gradually taking off the principal part of the whey, a little warm water is put upon the curd, which is left standing for a quarter of an hour. By increasing the heat and quantity of water, the cheese is made hard and more durable. All the whey and water is then taken off, and the curd is gradually packed hard into a form cut out by the turner, flatter and broader than the form for the Edam cheese. A wooden cover is placed over it, and the press, with a weight of about 8 lbs., put upon it. It is here frequently turned, and altogether remains under the press about twenty-four hours. The cheese is then carried to a cool cellar, put into a tub containing pickle, the liquid covering the lower half of it. The water for the pickle is boiled, and about three or four handfuls of salt melted in about thirty imperial pints of water. The cheese is not put in until the water is quite cold. After remaining twenty-four hours, or, at most, two days, in the pickle-tub, where it is turned every six hours, the cheese, after being rubbed over with salt, is placed upon a board slightly hollowed, having a small channel in the centre, to conduct the whey which runs off into a tub placed at one end. This board is called the zouttank; upon which several cheeses are placed at a time. About two or three ounces of the large crystallized salt is placed upon the upper side of the cheese, which is frequently turned, the side uppermost being always sprinkled with salt. It remains on the zouttank about eight or ten days, according to the warmness of the weather; the cheese is then washed with hot water, rubbed dry, and laid upon planks, and turned daily, until perfectly dry and hard.

The cheese-house is generally shut during the day, but must be open in the evening and early in the morning.

"Gouda is the principal market for this kind of cheese, where it sells at about 35s. per cwt."

"Each cow at grass in Holland is calculated to give about three or four pounds sweet milk cheese per day."

"We omit the method of making the Kanter cheese, which is similar to our skim-milk cheese, and of the cheese utensils."

"The milk-houses are generally between the dwelling and cow-house, in a square apartment, in a corner of which is the cooler; it is airy, roomy, and paved with square bricks, the upper part serving for churning, making cheese, &c.; and descending a few steps, into a sort of cellar, is the milk-room, having two or four windows, which are opened or shut according to circumstances."

"The cheese-houses are also generally cellars, kept clean and well ventilated."

"The Dutch are remarkably particular as to the quantity and quality of their salt, of which there are three kinds manufactured; and it is this, our reporter thinks, which is the principal cause of the sweet and delicious flavour of their butter, which, although well-flavoured, hardly tastes of salt, or, rather, of that acrid quality which is perceptible in the butter of Great Britain."

"Cleanliness governs in all the Dutch dairies. Every dwelling-house is a model and a pattern. They seem to vie with each other on this point. The cow-house is pure and clean, not a particle of filth being to be seen in it; the cows, says Mr. M., are as clean as if they were in a dining-room; the milk and cheese-houses, and, in short, every part of the house, are free from dust and dirt of any kind. The whole apartments, even the byre (stalls) and hay-house, are generally under one roof; and the cleanly system and the admirable arrangement give that comfort and pleasure which are too often wanted in other countries." See Buel's Farmers' Instructor.

The Journal of the English Agricultural Society contains an article on the rural affairs of some parts of Holland, in which an excellent account is given of the Holstein mode of making the butter which is so very famous. The Holstein dairies are very extensive, varying from 100 to 400 cows, and provided with buildings and every necessary accommodation on a corresponding scale. Whenever practicable, the milk room or cellar is made to face the north, and sufficiently capacious to hold the proceeds of at least four milkings. The brick or tile floors have already been described. Numerous windows or air passages are prepared so as to secure the most perfect ventilation; they are furnished with glass sashes and shutters, and within have gauze curtains to exclude insects.

When, as is sometimes the case, both cheese and butter are made at the same dairy, the apartment for cheese is always kept separate from that devoted to butter-making, from the vicinity of which last every thing is carefully kept away which by any possibility could exercise a sinister influence on the very susceptible substances of milk and butter, which suffer to a degree those unaccustomed to observe it little suspect from an impure atmosphere. The dairy is managed by women, of whom there is the superintendent, or head dairy woman; and one dairy maid to every eighteen cows. There is besides the owner or overseer, and one or more men who attend to the feeding of the swine. There are others whose business is to attend to the cows, see that they are properly fed, and every thing in its proper place and keeping. The overseer sees that the cows are fully milked, as on this the quantity and excellence of the cream is greatly depending. It has been ascertained by carefully repeated experiments that the first drawn milk contains five, the second eight, and the fifth seventeen per cent. of cream.

The business of the head dairy woman is arduous, and demands a full acquaintance with the various processes. "She must not only thoroughly understand, but accurately observe the precise time when the milk should be 2 L
DAIRY.

398

creamed; the degree of acidity it must attain in the cream barrels; its temperature, whether requiring the addition of warm water or cold to the churn; as well as the all-important operations of kneading, beating, salting, and packing the butter.” The milkings commences at four in the morning (the milkers rising at three), in the field, and the milk is conveyed to the dairy by a one horse wagon, from hooks on which large vessels are suspended. To prevent the milk from flying over the basin of these vessels in moulding the whey, a piece of wood, of nearly the size of the vessel, float on the milk, and this practice is adopted when pails are carried by the band.

The effect which vessels made of different materials has on the promoting or retarding the acidity of milk, has received much attention in Holland, and the vessels most generally preferred on all accounts are shallow wooden keelers, holding about eight quarts. In some few instances glass vessels are used, and some of the reports speak of them highly. It has been found that cream, to make first rate butter, must be removed from the milk before the latter gets at all sour, and that the cream will not fully rise under thirty-six hours; to prevent souring before that time, especially in sultry weather or during thunder storms, requires particular attention to temperature.

A cellar temperature of from 60 to 62 degrees gives the best and the most cream, the rising being completed in thirty-six hours; a greater degree of warmth hastens the process, but lessens the quantity of the butter; a lower temperature preserves the milk forty-eight or sixty hours, but imparts an unpleasant flavour to the cream and butter. The commencement of souring in milk is marked by a slight wrinkling of the cream, and a slightly acid taste. When this appears, whether the milk has stood longer or a shorter time, skimming commences. As fast as it is collected, it is screened through a hair sieve kept for this purpose alone, into large barrels of 240 quarts each, in which it remains till the necessary sourness is attained, which in summer usually takes twenty-four hours, and in winter thirty-six or forty-eight hours. During this advance to acidity, the cream is frequently stirred, to prevent its coagulating or becoming cheesy, and when fit for churning, the skill of the dairywoman is required to determine the proper temperature to make good butter. In warm weather the churn is rinsed with the coldest water, and if necessary cold spring water is added to the cream, but if the cellar is properly made, this is rarely necessary. In cold weather the churn is washed in warm water, and is sometimes applied to the cream itself. The churning being completed, the butter is immediately carried to the butter cellar, where, in a large tray or trough made of beech or oak highly polished, and provided with a plug at the lower extremity to let off the milk, the butter is slightly worked and salted with the purest salt, moulded with a ladle into a mass at the upper end of the trough, and left for some hours to drain. In the evening it is thoroughly kneaded and beat, the dairymaid lifting a piece of three or four pounds, and slapping it against the trough with great force to beat out the milky particles. After the whole mass has thus, piece by piece, been freed from the buttermilk, it is again spread out, and receives its full salting (in all about ½ ounce of salt to a pound of butter), which is worked with the utmost care equally through the whole, and is then moulded into a compact mass. Butter in Holstein is seldom washed, though in some other parts of Holland it is practised with the greatest success. When cream is made to fill a cask, the several churnings are once more kneaded and beat thoroughly together, a very little fresh salt is added, and it is then packed in the barrel, which is made of red beech wood, water tight, and previously well washed with water and salt. The cask must be filled at a single packing, each layer pounded down, and care being taken that no interstice is left between the butter and the sides of the cask. This packing of a cask at a time gives the butter of large cities the advantage over small towns, as it must be left longer exposed to air before the quantity requisite to fill the barrel is obtained.

“The qualities of first rate butter are considered to be, 1st, a fine yellow colour, neither pale nor orange tinted; 2d, a close, waxy texture, in which extremely minute and perfectly transparent beads of brine are perceptible; but if these drops be either large, or in the slightest degree tinged with colour, it indicates an imperfect working of the butter; while an entirely opaque, cloudy, or yellow appearance is equally disapproved; 3d, a fresh, fragrant perfume, and a sweet, kernelly taste; 4th, good butter will, above all, be distinguished by keeping for a considerable time, without acquiring an old or rancid flavour.

“The quality of food which can be afforded to the cows during winter is determined at the beginning of the season, when the harvest returns are known; and in plentiful years the advantage over small towns is marked by three sacks of grain (generally oats, at 140 pounds the sack), 3,000 pounds of straw, including bedding or litter for the stable, and 1,800 pounds of hay of good quality; while for every 100 pounds of hay deducted she must receive 25 pounds of grain more, and vice versa.”

During the winter the requisite colour is given to the butter by some colouring material; and the best for this purpose is found to be a mixture of annatto and turmeric, in the proportion of five ounces of the latter to one pound of the former.

The average quantity of milk from the Holstein cows is about 2,500 quarts per annum; much depending on the food and care; and it is calculated that every 100 pounds of milk will give 31 pounds of butter, 6 pounds of fresh cheese, 14 pounds of buttermilk, and 763 pounds whey, where cheese is made. Fifteen quarts of milk are considered a fair average for a pound of butter, though sometimes a cow gives milk so rich that 12 quarts make a pound.

(On the whole, it is considered a fair return from the Holstein dairy when the produce amounts to 100 pounds of butter and 150 pounds of cheese per annum to each cow.)

(Buck.)

The farmer will find a good article on the
dairy in Professor Low's Breeds of British Animals, a beautifully illustrated work, which should be patronised by all the Farmer's Clubs, as well as by those agriculturists to whom its price is not an object. The following authorities may also be consulted with advantage: "On the Meadows and Dairies of Holland." (Trans. High. Soc. vol. i. p. 202); "Reports upon Dairy Management," (Wld.) p. 341; vol. ii. p. 254; vol. iv. p. 406; Mr. Aiton "On the Making of Butter and Cheese in the Dairy District of Scotland," (Quart. Journ. of Agr. vol. v. p. 356, and Com. to Board of Agr. vol. iv. pp. 214-337); also the article "Dairy" in vol. vii. of the Penny Cyc. in Baxter's Lib. of Agr. Know., and in vol. iii. of British Husbandry, Lib. of Use. Know.

DAISY, COMMON, or DAY'S EYE (Bellis perennis). These large white gaucy-looking flowers are so universal in English pastures and meadows, that description is almost needless. They flower all the year, principally dotting the meadows early in May; in March they begin to be common, and after Midsummer to be less numerous. The root is slender, and the plant flowers from May to September. Double as well as prolific daisies are common in gardens, and the prolificer variety is now and then found wild. Domestic cattle scarcely touch this plant. Notwithstanding its beauty and its celebration by poets, the daisy is thought a blemish or intruder in neat grass-plats, and can be overcome by perpetual stubbing only. (Eng. Flor. vol. iii. p. 448.)

The most common daisies in the United States are that called Flea-bane, and by botanists Eri- geron strigosus, and the Horseweed or Butterweed (Eri- geron Canadensis). This last has an annual root, the stem growing from six inches to five or six feet in height, very hairy and much branched above. The flowers are white, and disposed in rays. In the Middle States it is a common weed in fields and on roadsides, flowering in August and September.

The daisy called Flea-bane has a biennial root, as some botanists believe, and is common in pastures and upland meadows, flowering in June and August. The flower consists of white rays. It is a very common and worthless weed, especially in the first crop of upland meadows after a course of grain crops. (Flor. Cist.)

Another species of daisy called the Handsome Eri- geron (E. pulchellus), is common on the borders of woods and thickets, where it flowers in the Middle States in May and June. Its root is perennial, and the whole plant is somewhat hoary. The rays composing the flowers, which are large, are of a pale bluish purple.

Some ten or twelve additional species of eri- geron have been found in the United States. (Flor. Cist.; Nuttall's Genera.)

DAISY, MOON, or MIDSUMMER DAISY (Chrysanthemum leucanthemum). The Ox-eye Daisy, or white-flowered chrysanthemum (Pl. 10, w), is a vile weed introduced into the United States from Europe. In many parts of the country it is spread wide and far, constituting a serious nuisance.

DAM. The mother of any young domestic animal. Also a mole or bank to confine water. See ENRANKMENT.

DAMSON. A small, useful, black plum, brought originally from Damascus, whence the name.

DANDELION, COMMON (Taraxacum terrestrum). A corruption of the French name dent de leon, or lion's tooth. An indigenous, perennial plant, growing in meadows and pastures, on roadsides, ditch banks, and indeed everywhere. Root tap-shaped, very milky, externally black, difficult of extirpation; leaves numer- ous, spreading, of a bright shining green, quite smooth, and they may be called lion- toothed; flowers one and a half inches wide, of a uniform yellow colour, which blow from April to August, and have the remarkable property of expanding early in the morning in fine weather only, and closing in the evening. (Eng. Flora, vol. iii. p. 319.) It is a valuable medicine, is aperient, powerfully diuretic, and alterative in its qualities, and, if persevered in, is excellent in liver complaints; it must be taken in decoction, or in the form of extract. Its de- obstruent influence in torpid conditions of the liver is striking; but its use must be persisted in for a considerable length of time. It should not be used after the first of May, as it is apt to derange the stomach.

By culture, and especially by blanching, this herb, though, like the garden lettuce and en- dive, originally full of bitter mill, becomes sufficiently mild to be eaten in a salad, nor is its bitterness of a disagreeable kind. In France the roots and leaves are eaten with bread and butter. The marsh dandelion (L. palustris), is another species, smaller in size than the foregoing, and naturally a bog plant, growing in low boggy meadows. Dandelion is relished by goats, and especially by hogs, who devour it eagerly; but sheep and cows dislike it, and horses totally refuse it. (Willich's Dom. Encyc.)

DANDELION HAWKBIT (Apargia tarax- acci). See HAWKBIT.

DANDRIFT. A species of scurf which is brushed out in grooming the horse, and consists of scales or portions of the cuticle, or scar skin, detached in its gradual change or renewal.

DANEWORT, or DWARF ELDER-WALL-WORT (Sambucus ebulus). The green leaves of this European plant have a narcotic smell, and are said to expel mice from granaries; nor will moles come where these leaves or those of the common elder are laid. Cattle will not eat the foliage. Its berries impart a violet colour, and their juice, mixed with vinegar, dyes raw linen, as well as morocco leather, of an azure blue. (Eng. Flora, vol. ii. p. 108; Willich's Encyc.) This perennial plant is frequently mistaken for the common elder. It grows four or five feet high, and dies away every autumn to the ground. The stalks are green and round, very like the shoots of common elder; but having no woody part about the plant, they rise green from the ground. The leaves are longer than common elder leaves, and they are serrated round their edges. The flowers are small and white, succeeded by black berries, which the birds rarely suffer to ripen. It loves untilled ground, hedgeways, &c., flowering in summer, and ripening its berries in autumn.

DANGEROUS ANIMALS. See NUISANCE.
DANNOCKS. A provincial name for hedging-gloves.

DAPPLE. A term sometimes used to signify marked with various colours.

DARGUE. A local word signifying the quantity of peat turf one man can cut and two men wheel in a day.

DARNEL (Bromus secalinus). Smooth rye brome-grass. (Bromus mollis, Pl. 7, b.) Soft brome-grass. Both these grasses pass in England under the common name of darnel. Professor Martyn suspects the annual bearded rye-grass (Lotobum temulentum, Pl. 7, 2), to be the darnel of the Romans (Virg. Georg. i. 159). Mr. Holdich, of the Farmer's Journal (Essay on Weeds), observes that he never found this grass among corn crops. Sinclair (Hort. Gram. p. 32), says, "I have found the Bromus mollis and Alopecurus agrestis, with the Bromus secalinus to be the most prevalent weeds (of the annual grass kind) in corn fields;" these, therefore, may be considered the darnel of the British farmer. In the Essay of Mr. Pitt, he treats of darnel as a plant which had often seen in wheat crops, and perfectly well knew. Dr. Withering, in his Botany, also mentions this darnel (Lotobum temulentum), as "common in corn-fields, mostly among barley and flax;" and that it is a very troublesome weed among wheat, in Norfolk and Suffolk. The doctor also describes another species of Lotobum (L. arvense), as being much like the other, only it is smooth, and calls it white darnel. (Pl. 7, d.) He observes that it is common in many parts and places, and "very injurious to a crop of wheat," for which he quotes Mr. Pitt's authority. Mr. Pitt, indeed, names his darnel white darnel, but immediately calls it L. temulentum. Both these are annuals, and flower in July and August. Now it seems never to have occurred to writers on this subject, that, when they were in any difficulty about agricultural weeds, they should have recourse to the characters of the seeds of the plants. It is quite impossible that any grass seed should be darnel, either ancient or modern, unless the seeds are heavy enough to resist the operation of dressing, and to remain in the wheat in part, in spite of all efforts to get rid of them. The ancients had wind and sieves, and they no doubt exerted themselves as much as possible to rid their wheat of such seeds as those of the L. temulentum, while such deleterious effects are ascribed to them if baked in bread, &c. Whether these plants be common in corn fields in any part of England, or whether, if they be, their seeds are heavy enough to remain in samples of wheat and barley, must here be left undecided. I can only say that, in all my experience, and as far as I have ever seen or heard from practical authority, I know of no darnel in England but the Bromus secalinus, and, less generally, the Bromus mollis. (Eng. Flora, vol. i. p. 151-3; Hort. Gram. Wob.; Sinclair's Weeds, p. 4.)

DARNEL (Lotobum). There are in England three species of darnel enumerated by Smith (Eng. Flora, vol. i. p. 178). The perennial darnel (L. perenne), common in meadows, pastures, and grassy ground, and well known to the farmer by the name of rye-grass or ray-grass. It yields an early crop of hay upon high or sandy lands, and makes a fine turf, which, however, is said not to be lasting except upon a rich soil. Much valuable information concerning this cultivated weed merits the meries of Professor Hooker in his continuation of the Flora Londinensis. The result seems to be, that the grass is best suited to the light land of Norfolk, where it first obtained its reputation. See Rye Grass. 2. The bearded darnel (L. temulentum), the seeds of which are of very evil report for causing intoxication in men, beasts, and birds, and bringing on fatal convulsions. Haller speaks of them as communicating these properties to the grain, whether of rye or rye-grasses, depending on the effects being sometimes so violent as to produce convulsions. In Scotland the name of Sleepies, is applied to darnel, from the seeds causing narcotic effects. In England and America these effects have never been known to arise from eating flour made from wheat containing cheat. It is evident that the enemy of the grain crops called darnel, chess, and cheat is not the same plant in all countries, probably for the reason that different species of grasses somewhat resembling each other in external characters may be more favoured by circumstances of soil and climate and exposure in some places than in others. Cheat or chess is evidently a more hardy plant in resisting the effects of frost than wheat or rye, which often die in situations exposed to cold or other unfavourable influences, leaving the darnel, which, from some resemblance in the plant before heading, is thus supposed to be degenerated wheat. On the other hand, however, the soil is rich and the other circumstances favourable to the growth of wheat and other winter grains, these spread first over the ground and keep down the cheat or chess, or brome and rye-grasses, at least until after harvest. Not only does the idea prevail that wheat and other cereal grains degenerate to darnel, but also to spelt, well known to be a peculiar and very inferior species of wheat, of hardy growth, and much cultivated in some parts of Europe, especially in mountainous districts. Thus, we find that to believe the evidence of common observation, wheat degenerates into spelt in some countries, and in others into a species of Bromus, fuscure, or that species of rye-grass (the Lotobum temulentum) which is endowed with intoxicating qualities, all being designated as the wheat enemy, darnel. Nothing analogous to such metamorphosis can be found in nature, neither can it be fairly believed that such degeneration is possible, until some one makes a crucial experiment. It belongs to the credulous to afford the demonstration. For more particular information in regard to cheat or chess in the United
States, see Dr. Darlington's Flora Cestrice, under the head of Bromus scolacinus, Rye bromus, Cheat or Chess.

DARTARS. In farriery, a sort of scab or ulceration taking place on the chin, to which lambs are subject.

DAUBING. A word meaning provincially plastering with clay.

DAUBY. A word applied to land when wet, signifying clammy or sticky.

DAYING. A provincial word applied to the getting of marl out of the face of the cliffs on the sea-coasts, when it is drawn up by a wince.

DEADLY NIGHTSHADE. See Belladonna and Nightshade.

DEAD-NETTLE (Lamium). A genus of perennial or annual European herbs, of which twenty species are described. Among which, are the white dead-nettle (L. album) and red dead-nettle (L. purpureum) to which medicinal properties are ascribed. The herbage of the former is scarcely eaten by cattle, and has a slightly fetid scent. The flowers abound with honey. Low says (Proc. Agr. p. 440) it is sometimes common in corn-fields, and having a strong, creeping, perennial root, it should be carefully extirpated.

DEAD-TOPS. A disease incident to young trees, which may be cured by cutting off the withered parts close to the nearest sound twig or shoot, and elaying them over, in the same manner as practised in grafting.

DEAF. A provincial word signifying blasted or barren, as a deaf ear of grain, a deaf-nut, &c. or such as have no grain or kernel. In such cases it is probable that the pollen has been scattered, and never communicated the fertilizing principle to the seed, which resembles in this respect an addle egg.

DEAL (Sax. dealan, to divide; Ger. dielen; Dutch, deelen; Dan. doeler). The small thickness into which a piece of timber of any sort is cut up; but in England the term is now improperly restricted in its signification to the wood of the fir tree, cut up into thicknesses in the countries whence deals are imported.

DEATH-WATCH (Aunobium tessellatum; Tenebrion piceosphorum Lin.). The popular name in England for a small insect that harbours chiefly in old wood. It is produced from a very minute white egg, hatched in March; in the perfect state these insects are about 1/10th of an inch in length, and of a dark brown, spotted colour. They make a ticking noise, which is an expression of mutual affection between the male and female, but which has and is still superstitiously imagined by some to be an omen of death. See Peaty Cyclo. vol. viii.

DEBRIS (Fr. débris). In geology, any loose materials, such as fragments of rocks, ruins, or rubbish.

DECAV. All vegetable as well as animal substances undergo two processes of decomposition after death. One of these is named fermentation, the other decay, putrefaction, or eremacausis. The decay of woody fibre (the principal constituent of all plants) is accompanied by a phenomenon of a peculiar kind. This substance, in contact with air or oxygen gas, converts the latter into an equal volume of carbonic acid, and its decay ceases upon the disappearance of the oxygen. If the carbonic acid is removed, and oxygen replaced, its decay recommences, that is, again converts oxygen into carbonic acid. Woody fibre consists of carbon and the elements of water; and if we judge only from the products formed during its decomposition, and from those formed by pure charcoal, burned at a high temperature, we might conclude that the causes were the same in both: the decay of woody fibre proceeds, therefore, as if no hydrogen or oxygen entered into its composition.

A very long time is required for the completion of this process of combustion, and the presence of water is necessary for its maintenance: alkalies promote it, but acids retard it; all antiseptic substances, such as sulphurous acid, the mercurial salts, empyreumatic oils, &c., cause its complete cessation.

Woody fibre, in a state of decay, is the substance called humus.

The property of woody fibre to convert surrounding oxygen into carbonic acid diminishes in proportion as its decay advances, and at last a certain quantity of a brown cold-looking substance remains, in which this property is entirely wanting. This substance is called woad; it is the product of the complete decay of woody fibre. Mould constitutes the principal part of all the strata of brown coal and peat.

Eremacausis (from ἑρέμω slow, and καύσω, combustion) is the act of gradual combination of the combustible elements of a body with the oxygen of the air; a slow combustion or oxidation never ceases.

The conversion of wood into humus, the formation of acetic acid out of alcohol, nitrification, and numerous other processes, are of this nature. Vegetable juices of every kind, parts of animal and vegetable substances, moist sawdust, blood, &c., cannot be exposed to the air, without suffering immediately a progressive change of colour and properties, during which oxygen is absorbed. These changes do not take place when water is excluded, or when the substances are exposed to the temperature of 32°, and different bodies require different degrees of heat, in order to effect the absorption of oxygen, and, consequently, their eremacausis. The property of suffering this change is possessed in the highest degree by substances which contain nitrogen.

(Liebig, Org. Chem. Part 2d.)

In the Appendix to the Third Report of the Agricultural of Massachusetts, 1840, Dr. S. L. Dana adds the following example, to show that even with the presence of moisture, vegetable matter will not decay, if air is excluded. A piece of a white birch tree was taken from a depth of twenty-five feet below the surface, in Lowell. "It must have been inhumed there probably before the creation of man, yet this most perishable of all wood is nearly as sound as if cut from the forest last fall." See Nitrification.

DECIDUOUS (Lat. decidu, I fall off). In zoology, a term applied to parts which have but a temporary existence, and are shed during the winter.
DEER.

The general name of animals of the stag kind, of which there are several species. These may be primarily divided into two groups; of which one has the horns with a single edge, and the other the double edge or less flattened, the others those with rounded antlers. The elk is the most characteristic species of the first group. The reindeer differs from the rest of the genus in the presence of antlers in both sexes, and in the great development of the brow-antlers. The third species of deer, referable to the flat-horned group, is the English park, the fallow-deer (Cervus dama, Lin.). The period of gestation in the fallow-doe is eight months. We have in England two varieties of the fallow-deer, which are said to be of foreign origin; the beautiful spotted kind, and the deep brown sort. These have multiplied exceedingly in many parts of the kingdom, which is now become famous for venison of superior fattiness and flavour to that of any other country in the world. The spotted deer of the Dama species must not be confounded with the spotted deer brought from India, which is a distinct species, namely the Cervus (Laxis) naculatus, and never changes its spots, whereas the spotted fallow-deer becomes a uniform brown in winter. This species has been domesticated in England, and propagates freely in parks. It is smaller and more elegant in form than the fallow-deer, and furnishes as good venison. Of the species of deer of which the beam of the antler gives a rounded form in section, the red deer (C. elaphus) and the roe-buck (C. capreolus) are indigenous species. The male red deer, in the language of "the noble art of venerei," is called a "hart," and the female a "hinds." She goes with young about a week later than the fallow-doe, and brings forth in May a single fawn, rarely two. The young of both sexes are at first styled "calves." In the common stag, or red deer, the shedding of the horns takes place about the end of February, or during March. The fallow-deer sheds his horns from about the middle of April to the first weeks of May. The roe-buck is the smallest species of European deer; the male is monogamous, and the female bears forth two fawns. They are not confined to the Scottish moor plains, being still found in some of the rugged places of Cumberland and Cumberland. The roe-buck in its native wilds does not keep in herds in its perambulations; but it only congregates in low coverts. The food of the roe-buck in the Highlands of Scotland is the Rhus saxatilis, or roe-buck-herry; but in winter they browse on the tender twigs of the birch and the fir. The flesh of the roe-buck is tender and delicate, when the animal has been hunted. The horns are used for handles of knives, and other instruments. Three varieties of the genus Cervus are possessed objects of the chase; the stag, the fallow-deer, and the roe-buck; each of which have long been followed with great ardour, according to the tastes of different sportsmen, and their means of gratifying them: the roe-buck is, however, becoming scarce.

The following notice of the several kinds of deer found in the United States, is chiefly condensed from Dr. Harlan's "Fauna Americana."

1. The Moose (Cervus alces), is by some called elk. It is the largest species of the deer kind, and is distinguished from all others by having broad and flattened horns, and a hairy tuft and mane. It is quite a domesticated animal, and their means of gratifying them: the roe-buck is, however, becoming scarce.

Moose live in small troops, in swampy places. Their gait, which is commonly a trot, is much less active than that of other deer. They live upon the buds of trees, moss, and some kinds of plants. In eating from the ground they are compelled, from the shortness of their necks, either to kneel or separate their fore-legs. They rut about the end of August and the month of September. The females bring forth from the middle of May to the middle of June, generally two and sometimes three, and occasionally only one, at a time. In the old female shed their horns annually, in January and February, and the young in April. They live 15 or 20 years. This species of deer is met with at present only in the more northern parts of the United States, and beyond the great lakes.

2. The Reindeer (Cervus tarandus), has a total length of 5 feet 6 inches; the horns are 2 feet 10 inches long, and 2 feet 2 inches apart at their summits. Their size is about that of the common deer, the legs being thinner in proportion, the horns shorter and thicker, the neck is very short. The colour varies according to the seasons and age of the animal. The

DECOMPOSITION.

The reduction or dissolution of any mixed body to the separate parts of which it is composed. It is of great importance to be assured, that, in every process of decomposition, whether by heat or by putrefaction, nothing is lost, nothing is ultimately destroyed; the components of the decomposed substance form new compounds. Decomposition is therefore not, in strict language, a destructive process; but merely a change of affinities, and a transformation of old into new compounds.
DENMARK.

DEER.

The adult is of a deep brown in the spring, passing, as the season advances, to a grayish-brown, and grayish-white, and during the warmest portion of the summer, is almost white.

The Rein-deer is the only animal of the deer genus which has been subjugated by man. The Laplanders have large troops of them. The greater part of the males are castrated and harnessed to sledges. The females furnish milk, the flesh food, the skins clothing, cordage, &c.

In America, however, the Rein-deer has never been domesticated for use. The male adults and sterile females lose their horns in winter, and the new ones are not perfectly hard and matured till August. They carry their young 33 weeks, at the end of which time, generally in the month of May, they bring forth. They abound in the northern regions, but are not found in the United States south of the state of Maine.

3. The Elk (Cervus Canadensis) called also the Canadian or American stag, inhabits Canada, Missouri, and other western states. The head of this species very much resembles that of the common deer. Its height at the withers is 4 feet; length of its branched horns 3 feet to 3 feet 10 inches; length of the tail only 2 inches. A black spot or mark descends from the corner of the mouth on each side of the lower jaw. The prevailing colour of the body above the flanks is a clear bloody-red. The female has no horns, and its colours are less strong. The elk associate in families. The females bring forth in the month of July. A fine specimen preserved in the Philadelphia museum, 13 years old, measures from the tip of the nose to the base of the tail 7 feet 7 inches.

4. The Virginian Deer (Cervus Virginianus), is the common deer found throughout the United States wherever extensive forests remain. It is met with as high north as Canada, and passing southwards through the Isthmus, is even seen on the river Oronoco, in South America. Its total length is 5 feet 5 inches; the horns, measured following the curvatures, are 1 foot 10 inches long; these are provided with antlers or branches; the tail is 10 inches in length; the weight of the animal ranges from 90 to 120 lbs. Its form is light, and its motions quick and exceedingly graceful. The colour of the young animal is of a deep brown, with small white spots; the adults in summer are of a beautiful brown or fawn colour, whilst the belly, sides of the thighs, and lower part of the tail remain white. They take their winter coat in October; their summer dress in March and April; their horns fall off in February; they carry their young nine months, and bring forth in July or August. Towards autumn the fawn loses its spots, and the hair becomes grayish, a state to which the hunters apply the phrase in the gray. The coat is shed in the latter part of May and beginning of June, and is then substituted by the reddish coat; in this state the animal is said to be in the red. Towards the last of August, the old bucks begin to change to the dark bluish color. The doe commences this change a week or two earlier; in this state they are said to be in the blue; this coat gradually lengthens until it comes to the

grey. The skin is said to be toughest in the red, thickest in the blue, and thinnest in the grey; the blue skin is most valuable. The horns are cast in January; they lose the velvet the last of September, and beginning of October.

This species displays great enmity towards the rattlesnake, which enemy they attack and destroy with singular dexterity and courage; when the deer discover one of these reptiles, they leap into the air to a great distance above it, and descend with their four feet brought together, forming a solid square, and light on the snake with their whole weight, when they immediately break away; they return and repeat the same manoeuvres until their enemy is completely destroyed.

In Pennsylvania, by act of Assembly, the killing of deer is restricted to the period between the 1st of August and the 1st of January, and similar enactments exist in other states. Deer are very timorous animals, and the hunter must be intimately acquainted with their habits and haunts. To approach them, even with the rifle, he exercises an instinct, which he has patiently cultivated, but little inferior to his dog. During or after a shower is chosen as the most favourable season for deer-stalking; both as a time when the deer will be more readily met with on the ridges, and that the noise made by the steps of the hunter may be drowned in the droppings from the trees. Their fondness for salt is also often employed for their destruction. A rotten log is salted, and when the hunter perceives that it is much frequented, he conceals himself within rifle-shot near it; or if it bears the marks of being recently visited, with a keen and intuned eye, he traces them to their lair. In October, November, and December the venison is best, if the weather has been mild; but after the country has been covered for some time with snow, it generally acquires an unpleasant taste, from their browsing upon the laurels (chiosodontibus undulatus) of the swamps.

5. Great Tailed Deer, and Mule Deer, inhabits the most remote northwestern territories of the United States. (Fauna Amer.; also Long's Expedition to the Rocky Mountains, vol. 2.)

6. The sixth species of the American deer, having become extinct, is now only met with in a fossil state. Part of a skeleton having been sent by President Jefferson to the late Professor Wistar, the bones are described by the latter in the Transactions of the American Philosophical Society, vol. 1, new series. It possessed many of the characters of the elk (Cervus Canadensis). The bones of this fossil elk have hitherto been discovered only in the morass near the falls of Ohio, called Big-bone-lick, in company with the bones of the mastodon, &c. (Hortan's Fauna Americana.)

DEER-NECK, in horsemanship, signifies a thin ill-formed neck.

DENMARK. The agriculture of Denmark, especially of the duiches of Slesvic, Holstein, and Lauenberg, has been described by Mr. Cott. A large portion of this extensive district is alluvial soil, of a very fertile description, composed of...
DEW.

The size of the farms varies between 50 and 200 acres, a portion of which is commonly left for eight or ten years in pasture. The meadow in April and May is not uncommonly let for two guineas per acre. The usual rotation of crops commonly followed is, after grass, oats, fallow, winter barley, rape for seed, wheat, oats, beans, oats. The Danes plough deep, with four heavy horses; crops usually heavy, often returning as much per English acre, according to Mr. Carr, as—

This, however, seems an enormous produce. Their horses, sheep, and cattle are large, but coarse. Jutland is the greatest breeding district, the cows commonly yield from thirty to forty quarts of milk per diem. Their implements of husbandry are poor. The wheel ploughs, with wooden mould-boards, are drawn by two horses. The harrows, with the exception of the brake, have generally wooden teeth. The rotation on arable lands, is follow dunged, rape seed, wheat or rye, barley, oats. In reference to seeds, red clover is sown in the proportion of 8 lbs. timothy or rye-grass 6 lbs. per acre. Clover is made into hay; and then pastured for four years. There are three distinct breeds of cattle in these dukedoms. 1. The nave cow, middle sized with not very long legs, fine head and horns, moderately thick neck, colour usually red or brown: these give most milk in proportion to their food. 2. The marsh cows, of a larger size, larger boned, colour red, requiring luxurious pasture, giving, when in full milk, twenty-four to thirty-two quarts per day, but their butter is smaller in quantity and of inferior quality to the others. 3. The Jutland cow, of fine bone, rather long body, colour gray or dun, more valued for its fattening than its milking qualities. (Journ. of Roy. Agr. Soc. vol. ii. p. 371.)

DEWSHIRING or DEVONSHIRING. A term formerly used for the operation of paring and burning.

DEVILS-BIT SCABIOUS (Scabiosa succian). This perennial weed, delighting in moist pastures, woods, and hedgeways, grows a foot high, with slender stalks and dark purplish-blue flowers, often milk white, resembling the garden scabious. It is also frequently seen in grain-fields. The stalks are round, firm, and upright, divided into several branches, and having two small leaves at each joint. The "wax" which grow from the root are four inches long, dark green, harsh, and somewhat hairy. The root is blackish, tapering, the end appearing bitten off. It was called "Devil's-bit," from the idea among the superstitious of the olden time that the devil had endeavoured to seize upon a plant so useful in its properties to mankind, but could not effect his purpose. He only bit off a piece of the root in the struggle, and carried with it all the virtue of the plant. (Eng. Flor. vol. i. p. 194.)

The plant known by this name in the Middle States, is the Helonias dioica of Pursh, the Veratrum viride of Muhlenburg, commonly called Blazing Star. It has a perennial root, and is frequent in woodlands and meadows, where it flowers in May and June. The root of this plant is bitter, and a tonic of some value. (Flor. Cestrica.)

DEW (Sax. deap; Dutch daauw; Germ. dauen, moisture). The deposition of water from the atmosphere during the night upon the ground, leaves of trees, and plants, blades of grass and other objects on or near the surface of the earth. The phenomena of dew have been considered by all writers on Meteorology, from Aristotle downwards; but they were first successfully investigated by the late Dr. Wells, who gave the true theory of the meteor in an admirable essay on the subject, first published in 1814. Dew does not fall from the atmosphere like rain, but forms in very different quantities on different substances; thus, on metals, it is sparingly deposited; on glass it forms abundantly, as it does also on straw, grass, cloth, paper, and other similar substances. Animal substances are among those which acquire dew in the greatest quantity. The temperature of grass covered with dew is always lower than that of the surrounding air. On calm and very clear nights (the period when dew is deposited most abundantly), Dr. Wells very frequently found the grass seven, eight, or nine degrees, and on one occasion, fourteen degrees, colder than the air about four feet above the ground. In England dew probably begins to appear upon grass, in places shaded from the sun, during clear and calm weather, soon after the heat of the atmosphere has declined; that is, three or four hours after midnight.

Very erroneous notions in regard to the manner in which dew is formed or deposited, have existed until a very recent period. This important agent in the promotion of vegetable life has been supposed by some to rise from the ground, whilst the phrase "falling dew," common in all languages, would seem to imply an almost universal belief that dew falls from the air, similar to the finest rain or mist. These general impressions have, however, been demonstrated to be incorrect, by the experiments of Dr. Wells; whose explanation of the causes operating in the production of dew is as simple as it is satisfactory. When substances not perfectly transparent, are exposed to the sun, they gain more or less heat; but when the sun goes down they part with their heat and become cold. The surrounding air, however, with its invisible vapour or moisture, being transparent, does not radiate or shoot off its heat, and hence remains comparatively warmer than bodies not transparent. Hence grass, leaves, wood, or stone, by growing or lying in the sun, have moisture to settle on them precisely for the same reason that it is deposited on the outside of a pitcher or glass containing very cold water.
The dew, therefore, is a deposit from that portion of vapour which enters into the composition of common air, and which is swept in contact with objects at or near the surface of the earth, like breath thrown upon the blade of a knife or other polished surface. When the sky is clear, as in starry and moonlight nights, then do grass, leaves, and other objects, throw off their heat most rapidly and become cooler than the air immediately above them, and the colder they get the more dew is condensed upon them. Different substances part with their heat more or less rapidly, and this explains the cause why different proportions of dew are observed on objects similarly exposed to the atmosphere. A gravel walk will have little or no dew upon it, whilst the grass on each side will be recking wet: because the grass not only radiates its heat more rapidly than the walk, but does not derive warmth from below to compensate for the loss. Besides, the moisture falling upon the gravel walk is absorbed more rapidly than the dew deposited upon plants.

The temperature at which dew begins to form is called the dew-point, and may be ascertained very accurately. Thus, by laying a thermometer on the grass in the evening, as the herbage parts with the warmth collected through the day, and gets colder, the moment little globules or particles of dew are observed on the grass, the degree at which the merency in the thermometer stands shows the dew-point or temperature at which the watery vapour condenses. It has been observed already, that grass possesses a faculty of radiating or parting with its heat very rapidly, on which account it quickly becomes considerably colder than the air immediately above. If, when a thermometer is placed upon the herbage, another is suspended in the air two or three feet above, this last will not fall so low by many degrees, the difference being sometimes as great as 10 or 15 degrees of Fahrenheit.

In making this experiment, the instrument suspended in the air must of course have its bulb covered from the sky by means of a piece of tin-foil, or other non-radiating substance, to prevent its heat from passing off, in which case the instrument would itself radiate, and thus represent its own temperature and not that of the surrounding air. It may be often observed that in the morning, whilst the grass is reeking wet with dew, a polished substance, lying upon it, such as the blade of a knife, will have little or no moisture on its surface. This shows that polished surfaces part with heat and become cooled down to the dew-point very slowly. The most dew will of course always be found on substances which have the power of cooling most rapidly, and few objects do this so readily as grass and the leaves of plants and trees.

The degree of cold necessary to be acquired by grass and other objects, before they can have dew deposited on them, can always be ascertained beforehand. Thus, take a thin tumbler of cut-glass, having polished sides; fill this about half full of pump or ice-water. Plunge into it the bulb of a thermometer, and the moment a film of dew or misty cloud is seen to form on the polished outside surface, note the degree at which the thermometer stands, and this will be the dew-point. Should pump-water be insufficient to cause a cloudiness on the polished surface of the glass, some ice may be added; or common salt and nitre, sal ammoniac, or some other substance employed in the production of artificial cold. The temperature at which atmospheric vapour condenses to form dew is generally several degrees below the temperature of the atmosphere. But this is only the case during clear weather, since, when there is a fog, or a rain, the dew-point will be found to correspond with the temperature of the air; showing that atmospheric temperature to the dew-point, will directly promote the condensation of its vapour or moisture into mist, cloud, rain, snow, or hail. The many relations which the dew-point, or degree at which vapour condenses, holds with atmospheric phenomena, may be understood from this. And let it be borne in mind that the dew-point is almost continually rising or falling, like the temperature of the atmosphere, being usually, in clear weather, some four, six, eight, or ten degrees lower than common air, as indicated by the thermometer.

The very simple means just described, by which the dew-point can be ascertained, approximately, with the aid of a tumbler and thermometer, is by no means the only mode practised for the purpose. On the contrary, it is the most primitive plan, and one requiring great skill and judgment to ensure tolerable accuracy. Mr. Daniels, a learned meteorologist, of London, several years since invented a contrivance called a Hygrometer, for determining the dew-point, which is rather complicated and too costly for general use. It will, we think, be entirely superseded by an instrument very recently invented by Prof. A. D. Bache, of Philadelphia, of which the following general description may furnish some idea.

One of the forms of this instrument consists of a square bar of highly polished steel, about half an inch in depth and breadth, and ten inches long, one end of which fits into a case attached to a box of tinned iron or copper. This box is to contain cold water, ice, or a freezing mixture, and is usually, for the season or rather to the temperature of deposition, or dew-point. The end of the bar which fits into the case has its temperature brought below the dew-point, while the other end is at the temperature of the air; one of the sections of the bar is, therefore, at the dew-point. Between this section and the box vapour is deposited on the side of the bar, and beyond it, in the highly burnished surface of the steel, appears in strong contrast, the line of junction being very well defined. To ascertain the temperature of the line where the deposit of dew commences, cylindrical holes are made perpendicularly downwards in the bar, at intervals of about half an inch apart, throughout the whole length, large enough to admit the bulb of a very small thermometer, and deep enough to carry the bulb entirely into the substance of the bar. If the line of deposition is opposite the middle of one of these holes, the thermometer then gives the dew-point; if between two of them, the
temperature at each hole is taken, by the same thermometer, or by two thermometers, and the proportional part of the difference corresponding to the distance of the dew-point line from the lower thermometer is added to the temperature observed by it. Care should be taken in making this observation to let the temperature of the different parts of the bar become stationary before registering them. In another form of the instrument, an iron or copper trough containing mercury is substituted for the bar; one side of the trough, which is best made square in its section, is of polished steel or gilded. The trough is attached to a tin vessel, as in the other instrument. When the surface is cooled down so as to obtain the line of deposit on the face of the trough, the bulb of a small thermometer, which may be moved along in the mercury within, is brought opposite to the line. The temperature which it denotes is, of course, the dew-point. See **Atmosphere and Hygrometer**.

**DEW-BERRY.** The fruit of the blue bramble (*Rubus caesius*), so termed from the resemblance of the glaucous bloom, or waxy secretion upon the black shining berries, to dew. (*Eng. Flor. vol. ii. p. 409.*) See **Bramble**.

**DEW-LAP** (from lapping or licking the dew). A term applied to the membranous fleshy substance that hangs down from the throats of new-castled. (**Dew Lap**).

**DEB**. An old English word for milk, now obsolete, but from whence we derive dairy.

**DIARRHCEA.** See **Diseases of Sheep, Cattle, and Horses**.

**DIASTASE.** When cold water is poured upon barley newly malted and crushed, is permitted to remain over it for a quarter of an hour, is then poured off, filtered, evaporated to a small bulk over boiling water, again filtered if necessary, and then mixed with much alcohol, a white tasteless powder falls to the bottom, to which the name of diastase has been given.

If unmalted barley be so treated, no diastase is obtained. This substance, therefore, is formed during the process of malting.

If wheat, or barley, or potatoes, which by steeping in water yield no diastase, be made to germinate or sprout, and be afterwards bruised and treated as above, diastase will be obtained. It is therefore produced during germination. (J. F. W. Johnston’s Lectures.)

**Diastase,** like sulphuric acid, possesses the property of transforming starch entirely, first into gum, and then into grape-sugar. One part of diastase will convert into sugar 2000 parts of starch. Seeds which have germinated always contain much more diastase than is necessary for the conversion of their starch into sugar. This excess of diastase Liebig thinks can by no means be regarded as accidental. One of the functions for which diastase appears to be created in the living seed to subsist, is to contribute to the wants of the young plant. “The starch in the seed,” says Johnston, “is the food of the future germ, prepared and ready to minister to its wants whenever heat and moisture concur in awakening it to life. But starch is itself insoluble in water, and could not, therefore, accompany the fluid sap when it begins to move and circulate. For this reason diastase is formed at the point where the germ first issues from the mass of food. There it transforms the starch, and renders it soluble, so that the young vessels can take it up and convey it to the point of growth. When the starch is exhausted, its functions cease, and it is transformed and carried into the general circulation. Or when, as in the potato, much more starch is present than is in many cases requisite, its function ceases long before the whole of the starch disappears. Its presence is necessary only until the leaves and roots are fully formed, when the plant is enabled to provide for itself, and becomes independent of the starch of the seed. When this period arrives, therefore, the production of diastase is no longer perceived.”

“This I have said is one of the purposes which appears to be served by diastase in the vegetable economy. That it is the only one we have no reason to believe. There may be others quite as interesting which we do not as yet understand. This is rendered more probable by the fact that the diastase contained in one pound of malted barley is capable of converting into sugar five pounds of starch. (Liebig.) It is the diastase in malt which dissolves the starch of the barley in the process of brewing; but as the diastase contained in malt is sufficient to dissolve so large a quantity of starch, it is obviously a waste of labour to malt the whole of the barley employed. One of malt to three of barley would probably be sufficient in most cases to obtain a wort containing the whole of the starch in solution. Advantage is taken of this property in the manufacture of the white beer of Louvain, and of other places in Flanders, and in Germany, where the light colour is secured by adding a large quantity of flour to a decoction of a small quantity of barley. And though at the temperature at which the seed germinates, more of this substance may be necessary to transform the same weight of starch than is required in our hands, when aided by artificial heat,—yet as we never in the ordinary course of nature find any thing superfluous or going to waste, there is reason to believe that the diastase may be intended also to contribute directly to the nourishment and growth of the plant. As it contains nitrogen, it must be derived from the gluten or vegetable albumen of the seed; and as a young plant of wheat, when already many inches from the ground, contains no more nitrogen than was originally present in the seed itself (Boussingault), this diastase may only be the result of one of those transformations of which gluten is susceptible, and by which it is rendered soluble, and capable of aiding in the production of those parts of the substance of the growing plant into which nitrogen enters as a necessary constituent.” (J. F. W. Johnston’s Lectures.)

**DIBBLE.** (from *dyapel*, Dutch, a sharp point). An instrument or conical stick to make holes in the ground for setting grain, plants, &c. “The old method of drilling by machinery,” say the Messrs. Ransome of Ipswich, “naturally suggests the consideration of whether the operation of dibbling may not be similarly accom-
plished. Many ingenious contrivances have from time to time been projected for this purpose, and several patents have also been obtained, but we are not aware of any that have been successfully and advantageously used.

DIBBLING is a mode of sowing grain, especially wheat, much practised in some parts of England. It is found to answer the best on the clover leys of the lighter districts, and least of land. It is performed by a man walking backwards with an iron dibble into each hand, with which he makes the holes, on the furrow slice, into which the seed is dropped by children, who place one or two seeds into each hole. By this mode there is a very considerable saving of seed, the quantity employed of wheat being usually from three to five pecks. The wheat plant obtains a more solid soil, and considerable additional employment is afforded to the labourer and his family. It is, however, a rather tedious process, and is not adapted to the stiffer descriptions of soil, for on these the dibble forms little cups, in which the rain is apt to lodge to the destruction of the seed grain. A good dibbler with three active attendants will plant about half an acre per day. The expense for labour is commonly about 7s. to 9s. per acre for wheat.

Dibbling was first pretty extensively introduced into the east of England about the commencement of the present century. It is spoken of as a novel practice in 1808, by Mr. Curtis of Lynn (Com. Board of Agr. vol. iv. p. 158), and by Mr. Pung of Sudbury, and Mr. Jones of Wellington, in Somersetshire (Ibid. 159); they had previously to this time made some rude attempts to employ the dibble near Yarmouth, in Norfolk, for, in 1784, Mr. Oxley describes the farmers of that district dibbling six, seven, and eight pecks per acre, in two rows on each furrow, by three or four droppers to one dibbler, at an expense of half a guinea per acre. (Young's Annals of Agr. vol. iii. p. 220.)

In Norfolk, and the neighbouring counties, broad-casting is now almost unknown. Mr. J. Barton, of East Leigh, Hampshire, says, 1836 (Hints to Schoolmasters, p. 2), I brought a man from Norfolk, twelve months ago, for the purpose of instructing my labourers in dibbling, and he brought with him the implements, which are made in the following manner. The body of the dibble is a core of hard steel, round which is soft iron, so as always to wear itself sharp; at the upper end is a handle. The instrument is three feet long, all iron excepting the handle; it weighs six pounds; a man walks with one in each hand backwards, and makes from 3000 to 3050 holes in a day, giving a slight twist with the wrist at the moment of plunging the iron into the ground, which makes a hole that does not again fill up by the crumbling in of the earth. The ground should be even, then the rows are dibbled, the holes four inches apart, so that four of them can be covered at once by the foot. The rows are about four and a half inches apart; the holes are filled by a rake, or harrow with a few bushes woven into it. I pay nine shillings per acre of 160 rods for the work, out of which the dibbler pays the child

ren who drop the wheat; three grains should be dibbled in each hole, which will take about one bushel and a half per acre. The Norfolk farmers say the yield by dibbling exceeds that by broad-casting by four bushels per acre.

Dibbling costs in Hertfordshire only 6s., and in Norfolk and Suffolk from 7s. to 10s. per acre, according to the distance of the holes, but when they are thickest, and there for four grains placed in each hole, it does not use more than two bushels of seed per acre.

A writer in the Mark Lane Express says, drilling wheat is the most generally practised in the eastern part of the county of Suffolk, and dibbling wheat has been upon the decline for the last twenty years; I believe, because it is more trouble to attend to dibblers than to drilling; but I was in the habit of dibbling wheat when I took business for myself in 1807, and I continue the practice to the present day, for the following reasons:—1st. It encourages the poor man and his family, by increasing his wages, and gives employment to his children which they would not have if wheat was drilled. 2dly, It shows the children, when young, that Providence has ordained them to get their bread by the sweat of their brow; and I grow upon the four-course shift 100 acres of wheat every year. For wheat I pay for dibbling 7s. per acre, which is done by seven men that have the largest families: those men earn 5l. each in five weeks, generally, but if the weather be fine in less time. Another and 3d reason why I prefer dibbling is, that the men and children tread the land with their feet, which makes the land firmer and better for the crop. 4thly, It is better to clean the land, because you can only hoe between the rows of the drilled wheat, when you can hoe all round the dibbled plant. 5thly, The seed goes farther into the ground from dibbling than drilling, the small end piercing deeper than it appears, while the drill appears deeper than it really is, as the upper part of the drill raising mould on each side, so that when harrowed the corn is not so deep as when dibbled. 6thly, There is always more under-corn, that is, small ears, from the drill than from the dibble, and dibbling takes less seed. Six pecks is about the quantity of seed it takes, unless it is very early in the season. I am a great advocate for dibbling, for the above reasons; I have tried both on the same field, and generally found the dibbled wheat the most productive; and it stands up better against the wind and rain:

| Thru dibbling saves half the 3 bushels usually | breadth

DICK, DIKE, or DYTE. A provincial word applied to the mound or back of a ditch, and dickle-hole is the excavation or ditch itself. In Scoto-Latin dickle is a stone wall. See DITCH.

DIGGING. See SPADE HATCHERY.

DIGITARIA SANGUINALIS. Pl. 7, f. Slen

407
der spikd finger-grass, or cock's-foot finger-grass. See Finger-grass and Crab Grass.

DISTEMPER. (Aneithum graveolens, from ΄Ενθήμ, on account of its running up straight). A plant kept in kitchen gardens in England. It flowers and seeds in August; the stalk is round, hollow, and upright, three feet high, and divided into many branches. The flowers are yellow and small, and stand in umbels on the top of its branches; the root is long. Its leaves and umbels are used in pickling, and the former in soups and sauces. It is a hardy plant, and if grown merely for decorative use may be cultivated in any open compartment: but if for seed, a sheltered situation, and a soil rather dry than damp, is to be allotted for it. It is propagated by seed, which is best sown immediately it is ripe, for if kept out of the ground until the spring, it is often incapable of germinating, or if plants are produced they usually decay without perfecting their seed; if neglected until the spring, it may be sown from the close of February until the commencement of May: the earlier the better. Thistles, however, the better. Dill may be sown in drills a foot apart, or broadcast, very thin and raked in. The plants are to remain where sown, as they will not bear removing. When of three or four weeks' growth they must be thinned to about ten inches apart; for if not allowed room, they spiral, their leaves decay, no lateral branches are thrown out, and their seed is not good.

To prevent these bad effects, in every stage of growth, they require to be kept clear of weeds. The leaves are fit for gathering as wanted, and the umbels about July and August. In September their seed ripens, when the umbels must be immediately cut and spread on a cloth to dry, as the seed is very apt to scatter. A volatile oil and a distilled water are procured from the seeds. Both are used as carminatives; the water is a good vehicle for powders prescribed for children. (G. W. Johnson's Kitch. Garden.) The kindred species called sweet fennel (Anethum sanctum) is by far the most esteemed. See Fennel.

DILLS. A provincial word applied to the common and corn sow-thistles, as well as to the taller hawk-weed.

DINGLE (from the Saxon, di^, or din^, a hollow). A small clough or valley between two steep hills.

DISEASES OF CATTLE. See Sheep, Horses, and Cattle.

DISTEMPER. This name, applied to certain well-known breeds of cattle, and especially sheep, is derived from the title of the paternal estate of the celebrated Robert Bakewell. The Dishley, is, therefore, synonymous with the Bakewell breed.

The name of this celebrated original improver of stock is too intimately associated with the history of a great agricultural interest, to be passed over without some particular notice.

Robert Bakewell was born about the year 1725, on his paternal estate at Dishley, in Leicestershire, and died there, October 1st, 1795. Though it does not appear that he contributed any thing to literature, even on the subjects to which he devoted his life, yet his efforts, particularly to improve the breed of sheep, justly procured for him a widely extended reputation. The cross breed which he introduced is well known as the Dishley, or new Leicestershire breed. He is to be distinguished from a Mr. Robert Bakewell, who, in 1808, published Observations on Wool, with notes, by Lord Somerville. (Penny Cyclop.; Genl. Mag. vol. lxxv. p. 909.) Of his cattle, Arthur Young remarked, in 1789 (and Young was no flatterer), when speaking of another excellent farmer—"His cattle are of Bakewell's breed, which is giving them sufficient praise." (Ann. vol. ii. p. 156.) And in the same volume, p. 379, when noticing his breed of sheep, he says, "I have not a doubt that it is, without any exception, the first in the world." To attain this excellence Bakewell devoted himself, travelling in search of stock to breed from, not only over England, but into Ireland and Holland. In 1787 his fame enabled him to reap some reward for these labours: for in that year he let three rams for 1250l, and was offered 1050l. for twenty ewes. The principles which guided him in the breeding of stock are given, in Ann. of Agr., vol. vi. p. 466, by Arthur Young, who twice visited him at Dishley. He kept constantly in view, in all his exertions, these objects—the most meat from the least food—the least offal, and the size of the best joints. He thought, it seems, that the pale-coloured beasts yielded finer meat than the dark ones: he was one of the first who generally introduced the practice of feeling stock under examination; not but what it was a practice partially adopted, even in the days of old Holinshed. Young describes, vol. viii. p. 473, the Dishley sheep, and Bakewell's neat cattle at p. 486, which were, perhaps, the finest of his day; and then his great heavy black cart horses, speaking of them as "by far the finest I have seen of that breed." Bakewell did much, too, in the construction of water-meadows. (Ibid. p. 490), and it is evident from his various observations reported by Young, that he was an enlightened and successful agriculturist, as well as breeder. The Dishley sheep have long been celebrated for their aptness to fatten, their quietude, and the smallness of their bones—they will long hand down the name of Bakewell as one of the farmer's best benefactors. Bakewell made no secret of his modes of improving stock, and rarely, if ever, entered into controversies with rival breeders. He wrote nothing himself: and the first scientific work on the subject was written by George Culley, in 1792, who formed himself on Bakewell's model. The examples of opulent and spirited proprietors have since continued to spread the improvements commenced by Bakewell, and followed up by Culley, Collins, Kline, and others too numerous to mention.

DISTIMPER is frequently used in the same sense as disease, but is particularly applied to cattle. In racing stables it is the distinguishing names for epidemic catarrh or influenza in horses. Bakewell, who in the early stage is recommended, and it is important that the bowels should be evacuated, and sedative medicines
given. (The Horse, p. 180.) In dogs distemper is one of the most fatal diseases; a little emetic powder (3 grains of opium) is recommended to be given (Clater’s Far., p. 292), followed by a dose once a day of 4, 5, or 6 grains of Turpith’s mineral.

DITCH (Sax. dic). A trench cut in the ground, usually round the fences of a field. Trenches of this kind are formed differently in various localities, but they should always be made so as to keep the water in them as pure as possible.

DIURETICS. In farriery, such remedies as have the power of forcing urine, that is, stimulating the kidneys to a moderate degree, so as to augment their secretory power. Nitri
dioxide of potassium, turpentine, cubebes, and juniper are diuretics. See BALL.

DOCK (Rumex). A large genus of perennial plants, of which ten are natives of Eng
l. The bloody-veined dock (R. sanguineus) has already been described under the head BLOODWORT. The curled dock (R. crispus), a very troublesome and unprofitable weed, abounds in waste grounds, pastures, and by
road- sides; root towering, yellowish stem, two or three feet high, somewhat zigzag; leaves smooth, of a lightish green; clusters of numerous rather crowded tufts or whirls of drooping pale green flowers. The sharp dock (R. acutus) is also not uncommon in low meadows and watery places. Root blackish and rather slender. The broad-leaved dock (R. obtusifolius) is a rank and very troublesome weed, common everywhere, which can only be conquered by stubbing up the root. Mowing is little pur
pose; stems a yard high; root black; many headed; yellowish within. The other docks are the golden dock (R. maritimum), the yellow marsh dock (R. palustris), and the great water dock (R. Hydrolylpathum). (Eng. Flor. vol. ii. p. 190.) All these docks are purgatives, and may be used instead of rhubarb. A decoction made with an ounce of the root of Rumex obtu
sifolius and a quart of water, reduced by boil
ing to a pint, then strained and sweetened, is a valuable remedy in that peculiar cutaneous affection called fish-skin disease (Ichthyoxy). Dock. A term signifying to trim the but
ocks, &c. of a sheep.

DOCKING. In farriery, the art of cutting off the tails of horses; and for a description of which see The Horse (Lib. Use, Know., p. 337).

DODDED SHEEP. Such as are without horns.

DODDER (Cuscuta Europaea). Pl. 10, c. The name of a species of bird-weed, which is not very commonly met with. This curious plant is unlike all others in appearance, having no leaves. The thread-shaped, red, or purple stalks, twining about other plants, headed with small reddish flowers, are easily to be recog
nised; they grow upon heaths and commons, intersecting the furze and nettles, and twisting themselves round every thing they can meet with. The common people, who speak truly, but not in courteys terms, call it devil’s-guts and hell-weed, because it does great damage among their tares and flax. The lesser dodder (C. epiti
thyrum) is of a similar habit, but smaller than the preceding.

This is the curious creeping plant or vine which was formerly so frequent and injurious to flax-crops in the United States, inter
	
tangling and spoiling whole lots of it; but since the culture of flax has so much diminished, dodder has become rare.

The American Cuscuta, Dodder, or Love-Vine, is also a singular parasite, which seizes upon any herbaceous plant which may be within its reach; but it is most commonly found in lo
calities where the snap-weed, spear-mint, and false-nettle occur. Its thread-like naked stems have some resemblance to brass, or copper
wire, and twine constantly against the apparent course of the sun,—or west, south, east. (Flor. Centrica.)

DOE. In the technical language of the hunter, the female of the buck or fallow deer. The female of the red deer is called a hind.

DOG (Lat. Canis). An extensive genus of animals, consisting of more than thirty species, of which that most generally known is the domes
tic dog (C. familiaris). The arrangement of M. Cuvier classes the dogs of the present day into three groups, dogs properly so called, wolves, and wof-dogs. It will be sufficient for our present purpose to speak of the dogs under three heads: 1. Farm dogs; 2. Hunting dogs; 3. Shooting dogs. The first includes the shepher
dog’s, the mastiff, and the bull-dog. The second, the terrier, the hound, the harrier, the beagle, and the greyhound. The third class
includes the pointer, the setter, and the spaniel. All these will be found noticed under their separate heads. That ingenious naturalist Mr. James Wilson has entered into the question of the origin of our domestic breed of dogs. (Quart. Journ. of Agr. vol. vii. p. 558—681.) Col. Hamilton Smith has also taken up the natural history of dogs. (Naturalist’s Lib. vols. xxv. xxvi. See a notice in the Quart. Journ. of Agr. vol. ii. p. 511.) All zoologists agree that there is no trace of the dog to be found in its primitive state of nature, although wild dogs exist in India and America. The great affinity to the wolf, and the period of gestation being the same, have led some to believe that the wolf is the original dog. The two animals will breed together; the young of both are born blind, and at the expiration of the same time, namely, 10 or 12 days, the puppies of both acquire the power of vision. But one fact ren
der this supposition at least doubtful,—none of the wild dogs, living in a state of nature, have ever returned to the true form of the wolf. The minute examination of this question, how
ever, would be out of place in this publication. In all the varieties of the dog, the following circumstances in his economy are constant: he is born with his eyes closed, he opens them on the 10th or 12th day; his teeth commence changing in the fourth month; and his full growth is attained at the expiration of the second year. The period of gestation is 63 days, and from 6 to 12 pups are produced at a birth. The dog is old at 15 years, and seldom lives beyond 20; his vigilance and bark are univer
sally known. The dog is liable to so many diseases, that to treat of them here would be impossible. Among the principal are the dis	
temper, rabies, canker in the ear, the mange, 2 M 409.
DOG BRAMBLE.  One of the provincial names of the weed corn-camomile.

DOG-FLY (Cynonia, Lin.). A genus of insects common in woods and among bushes, that is particularly troublesome to dogs, fastening upon their head and ears. They sting very severely, and always raise a blister in the part they touch.

DOG POISON, FOOL'S PARSLEY (Ehhusa cyprium).  Pl. 10, q. An umbelliferous plant, frequently found in gardens. It is easily distinguished from the other umbellifera by the partial umbels, consisting of three narrow, long, linear leaflets, which hang down. The leaves have short sheathing footstalks, are doubly pinnate, with decurrent, pinnatifid leaflets. It has been eaten for parsley, and has proved fatal. The stem and leaves are poisonous, and contain a peculiar alkali, called cypenia.

A plant under the same popular name is described by Dr. Darlington, as found in Chester county, Pennsylvania. (Flor. Cest.)

DOG'S CABBAGE (Thelygonum cynobrahim). A common garden soil suits this species; propagate by seeds.

DOG'S GRASS. See Cenoch.

DOG'S TAIL GRASS. See Cynosurus.

DOG'S TONGUE (Cynoglossum). See Hound's-tongue.

DOG'S TOOTH GRASS, CREEPING (Cynodon dactylon). Pl. 7, k. This grass was identified by A. R. Lambert, Esq. (Trans. Linnae Soc. vol. vi.) as the celebrated hallowed doob-grass of the Hindoos. In the East Indies this grass grows luxuriantly, and is highly valued as food for horses, &c.; in England, however, it scarcely begins to vegetate till the month of June, and experiments made by Sinclair and others show that its produce and nutritive powers here are not sufficiently great to hold out any hope that its valuable properties in the East Indies can be made available in the climate and soil of Britain. The doob-grass flowers in September, and the seed is ripe about the end of October, and sometimes in November. The plants, natives of the English coasts, flower about a month earlier than the above. It is found on the sandy shores of Cornwall abundantly, and was first noticed by Mr. Newton, in the time of Ray. (Hort. Gram. Wob. p. 290; Eng. Flor. vol. i. p. 94.)

DOG-WHEAT. See Cenoch.

DOGWOOD.  A name applied to two different plants: in England to any of the shrubby species of Cornus; in the West Indies to the Picuda crythisina. The former are of little interest, except as ornamental shrubs; the latter is a powerful narcotic, the real value of which in medicine has still to be determined.

There are two indigenous species of cornel or dogwood; the C. sanguinea, a bush of four or five feet high, with smooth branches of a dark red when full grown; fruit dark purple, very bitter, like every other part of the plant; found common in hedges and thickets, especially on a chalk or limestone soil; and the dwarf cornel (C. suecica), growing in moist

Diseases of the eyes, fits, diarrhoea, &c., all of which are treated of under their several heads.

In England, the shepherd's dog (C. fam. domesticus, Lin.) offers the example of one of the purest races of this domesticated animal, and that which, in its straight ears, its hair and tail, approaches nearest to the original stock. The sagacity of this variety in the peculiar department in which his services are rendered to man is well known, and has been illustrated by a hundred interesting anecdotes. It is a curious fact, that the brain of the shepherd's dog is larger than that of any other dog of the same race, but how far this is connected with his sagacity we shall not pretend to affirm. Notwithstanding the great variations in size met with in the pasture or shepherd's dog, in different countries of the globe (for he is probably the most extensively diffused of the race), yet he everywhere preserves some personal characteristics, which mark his adherence to the original type in a greater degree than in any other breed over which man has so arbitrarily exercised his dominion. One of these characteristics is his quantity of covering, which is invariably great, particularly about the neck. The large drover's dog, which attends the beast-markets, is larger, and usually of a stronger build than the shepherd-dog. The sagacious colly of Scotland is a dog deservedly prized, though much smaller than either the English sheep-dog or the drover's cattle-dog. The ears are never wholly pendent in any of the race; but in the British varieties, and many others also, they are half-erected, or half-pricked, as it is called. The prevailing colour is very generally gray, more or less dark; the tail is bushy, somewhat pendent, and recurved; visage more or less pointed.

DOG BRAMBLE (Ribes cynoibrati). One of a valuable genus of plants, which contains the gooseberry and the currant: some of the species are well suited for ornamenting shrubberies. They will grow in any soil, propagated by cuttings planted in autumn, or early in spring.

DOG-BRIER and DOG-ROSE (Rosa canina). The wild brier bearing the hip or hep.

DOG-DAYS, or CANICULAR DAYS. The name given to certain days of the year, during which the heat is usually the greatest. They are reckoned about forty, and are set down in the almanacs as beginning on the 3d July, and ending on the 11th August. In the time of the ancient astronomers, the remarkable star Sirius, called also caniculus, or the dog-star, rose heliacally, that is, just before the sun, about the beginning of July; and the sultry heat which usually prevails at that season, with all its disagreeable effects, among which the tendency of dogs to become rabid is not one of the least disagreeable, were ascribed to the malignant rage of this star. Owing to the precession of the equinoxes, the heliacal rising of Sirius now takes place later in the year, and in a cooler season; so that the dog-days have not now that relation to the particular position of the dog-star, from which they obtained their name.

DOG-FENNEL.  One of the provincial names of the weed corn-camomile.
alpine pastures, on the herbaceous stem four to six inches high. (Eng. Flora, vol. i. p. 221.) The English names of this shrub, says Phillips (Syl. Flora, vol. i. p. 183), are scarcely less numerous than the tints of its leaves. It is often called female cornel, to distinguish it from Cornus mascula, and hound's berry tree, dogberry, &c. (because, says Parkinson, the fruit is not even fit for the dogs), and hence the name of dogwood.

The Cornelian cherry (Cornus mascula) is a native of Austria, growing from fifteen to twenty feet high. See COrNELIAN CHERRY.

The American dogwood (Cornus Florida) is a small North American tree, the botanical name of which is derived from the horniness of its close-grained and firm wood. It is a very common undergrowth in woods, composed of deciduous trees. Very early in the spring, before the trees by which they are overtopped put out their leaves, the dogwood expands its beautiful white blossoms, and in such profusion as sometimes, at a distance, to resemble a snow-bank. The wood of this small tree is highly prized for a variety of useful purposes, among which is the making of cogs for mill-wheels. The bark is an excellent tonic, thought by some almost equal to Peruvian bark in its efficacy in curing intermittent fevers. A preparation called cornine has been extracted from it, very much resembling quinine. The unfolding of the blossoms of the dogwood is the signal to the American farmers to plant Indian corn.

Among the eight species of dogwood which have been described in North America, this alone is entitled by its size to be classed with the forest trees. It is the most interesting, too, for the value of its wood, the properties of its bark, and the beauty of its flowers. In the United States at large, it is known by the name of dogwood, and in Connecticut it is also called box wood.

"The dogwood is first seen in Massachusetts between the 42° and 43° of latitude, and in proceeding southward, it is met with uninterrupted throughout the Eastern and Western States, and the two Floridas, to the banks of the Mississippi. Over this vast extent of country it is one of the most common trees, and it abounds particularly in New Jersey, Pennsylvania, Maryland, and Virginia, wherever the soil is moist, gravelly, and somewhat uneven; farther south, in the Carolinas, Georgia, and the Floridas, it is found only on the borders of swamps, and never in the pine barrens, where the soil is too dry and sandy to sustain its vegetation. In the most fertile districts of Kentucky and West Tennessee it does not appear in the forests, except where the soil is gravelly and of a mudding quality.

"The dogwood sometimes reaches thirty or thirty-five feet in height, and nine or ten inches in diameter; but it does not generally exceed the height of eighteen or twenty feet, and the diameter of four or five inches. The trunk is strong, and is covered with a blackish bark, chapped into many small portions, which are often in the shape of squares more or less exact. The branches are proportionally less numerous than on other trees, and are regularly disposed nearly in the form of crosses. The young twigs are observed to incline upwards in a semicircular direction.

"The leaves are opposite, about three inches in length, oval, of a dark green above, and whitish beneath: the upper surface is very distinctly sulcated. Towards the close of summer they are often marked with black spots, and at the approach of winter they change to a dull red.

"In New York and New Jersey the flowers are fully blown about the 10th or 15th of May, while the leaves are only beginning to unfold themselves. The flowers are small, yellowish, and collected in bunches, which are surrounded with a very large involucre composed of four white floral leaves, sometimes inclining to violet. This fine involucre constitutes all the beauty of the flowers, which are very numerous, and which, in their season, robe the tree in white, like a full blown apple tree, and render it one of the fairest ornaments of the American forest.

"The seeds, of a vivid, glossy red, and of an oval shape, are always united. They remain upon the trees till the first frosts, when, notwithstanding their bitterness, they are devoured by the Robin, Turdus migratorius, which, about this period, arrives from the northern regions.

"The wood is hard, compact, heavy, and fine-grained, and is susceptible of a brilliant polish. The sap is perfectly white, and the heart is of a chocolate colour. This tree is not large enough for works which require pieces of considerable volume: it is used for the handles of light tools, such as mallets, small vises, &c. In the country, some farmers select it for harrow teeth, for the hames of horses' collars, and also for lining the runners of sledges; but to whatever purpose it is applied, being liable to split, it should never be wrought till it is perfectly seasoned. The shoots, when three or four years old, are found proper for the light hoops of small, portable casks; but the consumption in this way is inconsiderable. In the Middle States, the cogs of mill-wheels are made of dogwood, and its divergent branches are taken for the yokes which are put upon the necks of swine, to prevent their breaking into cultivated enclosures. Such are the profitable uses of this tree; it affords also excellent fuel, but it is too small to be brought into the markets of the cities." (Michael's North Amer. Sylva.)

DOLPHIN-FLY. The name in England of an insect of the aphis tribe, very destructive to beans. (See Beans.) It is sometimes called the collier. The destruction which this insect causes is not wonderful when we reflect on the astonishing fecundity of all the aphides family. The sexual intercourse of one original pair serves for all the generations which proceed from the female in the succeeding year; and Réaumur informs us, that, in five generations, one aphis may be the progenitor of 5,904,900,000 descendants: in one year there may be twenty generations. At one season they are viviparous, at others oviparous. The dolphin-fly or collier is of a black colour, it begins its depredations at the top of the bean,
and continues multiplying downwards. The only method of preserving the crop is to top the plants, and to burn the tops.

DOOB-GRASS. See Doe's Tooth Grass.

DOSS (a corruption of toss). A provincial word signifying to strike with the horn or gore slightly, as cattle frequently do each other. There are two species of pigeons, of which the principal varieties are the ring-dove or wood pigeon, the stock-dove, the rock-dove, and the turtle-dove. See Pigeon.

DOVE-COTE. A structure usually erected of wood for the accommodation and rearing of tame pigeons; the only essential difference between which and a common poultry house is, that the entrance for the birds must be raised to a considerable height from the ground, because pigeons fly higher in the atmosphere than most other birds.

The utmost cleanliness ought to prevail in pigeon houses, hence the holes should be carefully examined before the breeding season arrives. They should be frequently well washed out, and the dung and other impurities removed; but this should be done early in the day, when the birds are out, so that they may not be disturbed. Some old dove-cotes are circular buildings, of considerable size, with ranges of square holes formed in the anterior wall, in which the birds make their nests. From this feature in old dove-cotes, the term pigeon-holes in desks is arrived. These dove-cotes are entered by a door below; and by means of a ladder the young pigeons are easily taken from the nests. Many dove-cotes of this kind exist in Scotland. (Brandreth's Dict. of Science, &c.; Willich's Dom. Essay.)

DOWNS (Sax. dun; Erse, dun, a hill). In European agricultural parlance, large, open, elevated, unenclosed tracts of land, generally reserved for grazing purposes.

DOWNY LIME TREE (Tilia pubescens). A tree belonging to the southern United States. See Linden, and Lime Tree.

DOWNY OAT GRASS. See Avena.

DRAG. An implement of the harrow kind used in breaking down and reducing land into a fine state. Also an iron catch to fix on the wheels of heavily laden carts or carriages when descending steep hills or declivities.

DRAGON-FLY. A common name for the Neuroptera insects belonging to the genus Agrion or Libellula.

DRAINING. The very first care of the farmer, that on which the success of his future crops almost entirely depends, is the removal of unnecessary supplies of water—whether arising from the tenacity of the surface retaining too much water, or from springs exuding to the surface. For it is evident that as different crops require very varying quantities, so the culturator must adapt the moisture of the soil to the crops he purports to produce;—the DOVE. A mixture of pigeons, for instance, for the profitable growth of the rice plant, would destroy the meadow grasses of England;—and again the damp soils, of which many of the richest meadows of England are formed, would be much too moist for the cereal crops. The nature of the climate, the soil, and the subsoil must all be taken into account.

The plants growing on sandy soils, of course, will bear a much larger proportion of water than those vegetating on clay soils:—and thus the very soil which, in the dry eastern side of England, grows excellent crops of corn, would, in the western counties, where twice the amount of rain falls, on an average, than in the east, be found materially to injure the plants. (See WATER, its Uses to Vegetation.) Placed as the farmer is under such a variety of circumstances, cultivating lands of all kinds, it is useless, in this article, to attempt to assist him with more than general directions.

The water carried off the soil by artificial drainage is either by boring, by open or by under-ground drainage, or by both. Boring was first recommended by Elkington. It is chiefly adapted for low situations, surrounded by high lands, and merely consists in boring with an auger, or digging a well in the land intended to be drained, until a spring of water is pierced, whose head is lower than that of the surface of the field; and hence it follows that when the water is suffered to drain into the hole made by the auger, or the well, it of necessity drains from the land out of the bottom of the well, as fast as it flows into it at the top. This plan might be profitably employed to a much greater extent than at present. When combined with surface draining, it saves, by shortening the water channels, a considerable portion of the expense.

In open surface drains, the nature of the soil, its declinations, and its chemical composition can alone guide the farmer. In either case too much care can hardly be bestowed upon it; it is a question that the legislature has deemed to be of even national importance; for by the 3 & 4 Vict. c. 55, landowners possessing only limited interests in estates are empowered to raise money, by way of mortgage, on such property, to be employed for the purposes of improving them by drainage; and the government has promulgated the use of drain tiles by exempting them from duty. I shall confine my observations, therefore, chiefly to the formation of under-drains. These commonly vary in depth from 2½ to 4 feet; and, in peat soils, on account of the very material settling which takes place, as they are brought into cultivation, from this to 6 or 7 feet. The first operation necessary upon a field intended to be drained, is the examination of the strata, or veins of earth of which it is composed; and this is commonly effected with the boring auger, or by digging small pits, or open drains, as by this means the oozings or weepings will speedily display themselves, and indicate pretty correctly the source whence the superabundant water proceeds. This being ascertained, the direction of the under-drains will be the more easily decided. If the soil is of such a description that the subsoil plough can be used with advantage, then the top of the clay, brent, or clays, over which the strata form and preserved, should not be less than 2½ feet from the surface of the soil. In the formation of these drains the workman always com mences on the lowest extremity; by this means besides other advantages, the water, as he arrives at it, drains away from him, and shows

412
DRAINING.

him, by its escape, that he is preserving a proper fall. When the drain is cut to the requisite depth, he proceeds to fill it up with the materials through which the drainage waters are to flow, to within such a distance only as is out of the reach of the plough; and then the earth is shovelled back again over the drainage materials. The description of these materials, of necessity, varies with the nature of the country and its produce; in Essex, brushwood and straw are chiefly employed; in the northern parts of the island, stones, broken lime, or sandstone are used. Bricks and tiles are resorted to in districts where cheaper materials are not to be procured; and these are made in a variety of forms; and recently one or two valuable improvements have taken place in the construction of them by machinery; so that, by those of the Marquis of Tweeddale and Mr. Watchorn, draining tiles are now made at a very reduced price. Upon tile-making, in general, there is a good paper by Mr. Wiggins, Journ. Roy. Agr. Soc. vol. i. p. 315. The tiles of the Marquis of Tweeddale are described Trans. High. Soc. vol. vi. p. 50, and Journ. Roy. Agr. Soc. vol. ii. p. 148; and those of Mr. Watchorn, with engravings of his machine, in the Journ. of the Roy. Eng. Agr. Soc. vol. ii. p. 93; by which it seems that in Huntingdonshire the cost of the tiles made by his apparatus is about 1s. 6d. per 1000: this varies, of course, with the price of coals, of which variation Mr. Pusey has constructed the following table.

These are commonly used with the flat or sole tiles, which cost, in Huntingdonshire, from 8s. to 10s. per 1000. The clay best adapted for tiles is that which contains a small proportion of sand, or sand may be mixed with the clay. The annexed cut gives the shape of the Tweeddale patent drain tile. It is commonly made 3 inches deep, 3½ wide, and about 12 in

The subject of under-draining is, comparatively, so little understood in the United States, and its importance so great, that we are induced to subjoin the following additional information, chiefly condensed from that excellent work "The Book of the Farm, by H. Stephens," now publishing in Edinburgh.

The dimensions of tile-drains, depends entirely on the way these are to be constructed. If the bottom be hard and no soles are to be placed under the tiles, the drain may be cut narrower; and if nothing else but tile and earth are to be put into them before the earth is returned, they may be shallower. In regard to the employment of soles where the drain has a clay bottom, Mr. Stephens is strenuous in his as-
The length of drain-tiles varies in different parts of the country. Mr. Boyle's are 13 inches; the Duke of Portland's, in Ayrshire, and Mr. Beart's Godmanchester, Hertfordshire, 12 inches; and those from the Marquis of Tweeddale's machine, 14 inches, when burnt. If the price is the same per 1000, of course the 14-inch tile is cheaper than the 12-inch; but otherwise, the 12-inch is the handiest article in the manufacture, as being less apt to waste in handling, and twist when in the kiln; and their number is much more easily calculated in any given length of drain. The following table shows the number of tiles required for an imperial acre, of the different lengths made, and placed at the stated distances:

The numbers of each length of tile required at intermediate distances can easily be calculated from these data.

A representation of what Mr. Stephens considers the best formed drain-tile, and the manner of setting this on the soles, is given in a cut, where a, and b, are two 12-inch tiles, of the most correct shape, placed upon the soletiles, c.

The length of the tiles and soles being equal, their jointings are made in the middle of the soles, and this course is to be continued throughout. It is the practice of some tile-drainers, Mr. Stephens observes, to put a 3 inch sole under every joining of 2 tiles, leaving the intermediate space of the bottom without any sole, imagining that this will insure sufficient steadiness to tiles on what they call hard clay, whilst only half the number of soles are used. But this he pronounces a precarious practice.

In making the side-joinings of the tiles it has been usual to break a piece of the corner of 1 or 2 main-drain tiles, where side-drains are led into them. In breaking off the corners, there is a risk of breaking the entire tile. Another plan is to set 2 main-drain tiles so far asunder as the inside width of a common-drain-tile, and the opening on the other side of the tiles, if not occupied in the same manner by the tiles of another drain, is filled up with pieces of broken tiles or stones, or any other hard substance. This is perhaps a better plan than running the risk of breaking a number of tiles, and, after all, failing in making the opening suitable for the reception of the adjoining drain tiles. Both plans, however, Mr. Stephens pronounces very objectionable, and never to be resorted to where tiles, formed for the purpose of receiving others in their sides can be procured. Main-drain tiles of this description are made with openings on purpose to receive the shoudered end of the smaller sized side-drain tiles. To answer a similar purpose in particular situations where such tiles cannot be conveniently joined, two main and furrow or side-drain tiles are made of 1/4 and 1/4 lengths, which may be so arranged in regard to one another's position, as to conjoin the openings of both at the same place.

The junction of a common tile with a main-
DRAINING.

The drain to a river be too small, and there be risk, at times, of the overflows of the river sending back-water into the drain, the drain should be carried down as far by the side of the river as will secure a sufficient fall for it's purpose. Rather be at the expense of carrying the drain under a mill-course or rivulet than permit back-water to enter it.

A spirit level (see cut) has been found a very convenient instrument for ascertaining such a point, and generally for taking levels in fields. It is furnished with eye-sights a, b, and when in use is placed into a framing of brass, which operates as a spring to adjust it to the level position d, by the action of the large headed brass screw e. A stud is affixed to the framing, and pushed firmly into a gimlet-hole in the top of the short rod e, which is pushed or driven into the ground at the spot from whence the level is desired to be ascertained. It need scarcely be mentioned that the height of the eyesight from the ground is to be deducted from the height of observation, and which quantity is easily obtained by having the rod marked off in inches and feet; but it may be mentioned that this instrument should be used in all cases of draining on level ground, even where one is confident that he knows the fall of the ground, for the eye is a very deceitful monitor for informing you of the levelness of ground. Such a spirit level, well finished, costs in England, 15 shillings (or $4.25). Its whole length is 8 inches, depth 1½ inches, width or breadth, 1 inch. It is so light as to admit of being carried in the pocket, whilst its rod may be used as a staff or cane.

The cutting of the main-drain should be entirely finished before the tiles are laid in it, and immediately after it is finished, it should be measured with the drain-gauge, to ascertain whether it contains the specified dimensions and fall. This drain-gauge is an excellent substitute for the tape-line or foot-rule, which are both inconvenient for the purpose of measuring the dimensions of a drain. This simple instrument consists of a rod divided into feet and inches, with two arms fixed cross-wise, the length of which is to correspond with the required width of the drain. When this rod is put down to ascertain the depth, it is afterwards turned partially round, whilst its end rests on the bottom of the drain, until the ends of its arms touch the earth on both sides. If the arms cannot come round square to the sides of the drain, the drain is narrower than intended; and if they cannot reach both sides, it is wider than necessary. When made larger than intended, a greater expense may be incurred in filling up with stones, &c.

The person intrusted with the laying of the soles and tiles into drains, should be one who has been long accustomed to that kind of work, or otherwise a good workman, possessing judgment and common sense. He should remain constantly at the bottom of the drain and have a boy or other assistant to hand him the tiles and tools. After laying three soles in length, he must examine to see if they are straight in the face, and neither rise nor fall more than the fall in the drain. As a safe guide to him, where the fall is not decidedly cognisable by the senses, a mason's plumb-level will be found a convenient instrument. After three soles are thus placed, two tiles are set upon them, being so placed that their joinings shall meet on the intermediate spaces between the joinings of the soles.

The tiles for small drains are usually made, according to Mr. Stephens, about 3 inches wide and 5 inches high, inside measurement, which may be considered a large tile in places where these of nearly inches wide by 3½ inches high are used. The soles for small drains are made of different breadths, varying from 5 to 7 inches. They usually shrink about one-eighth in the kiln.

Several ingenious and efficient machines have been invented in Great Britain, which have greatly facilitated the manufacture of drain tiles and soles, and reduced their cost to the very moderate prices stated in the estimates presented. In the 12th volume of the Prize Essays and Transactions of the Highland Agricultural Society, descriptions of some of these will be found, illustrated with drawings. That invented by the Marquis of Tweeddale, and for which a gold medal was awarded him, will make 12,000 tiles in a day of ten hours, it being understood that the clay is previously prepared and milled, as in the common way, when three or even four men can only produce 1500 tiles in the same time. The machine requires a power only equal to one horse and the assistance of one man and two boys, one of these to feed in the clay and two to remove the tiles to the shelves.

The Essays, in the same volume, of Mr. Boyle and Mr. Taylor, upon the manufacture of draining tiles are well worth the attention of persons particularly interested in the subject, as they not only treat of the minutiae of the operations, but are illustrated with very numerous figures of the implements, mode of placing the tiles in the furnace, &c., &c.

Much capital has been wasted in the erection of tile-works, by those who have not at first known the best modes of proceeding, and employed men to manage them who knew little about the processes. Like most other kinds of business, tile-making and baking require a regular apprenticeship, in order to succeed properly. As the machine of Mr. Beart has
been highly approved of in Scotland, and seems so simple in its construction and mode of management, we think it perhaps better adapted to common purposes than the more formidable contrivance of the Marquis of Tweeddale. A description and cut of the instrument, by which 3000 tiles can be made in a day, with an explanation of the mode in which it is managed, will also be found in the 12th volume of the work to which we have just referred.

Mr. Stephens thinks that the very best method of draining land, is by the union of stones and tiles in the same drain. The width of the bottom of the drain covered with the sole, may be 7 inches; width at the top 12 inches; total depth 2½ feet, consisting of the drain-tile and covering of stones, packed with the hand above and on each side, extending 12 inches above the sole, leaving 18 inches to be filled in with turf and earth. Such a drain, when properly constructed, is pronounced the ne plus ultra of the art. But it is seldom done, either for want of the necessary supply of stones of the proper size, or the additional expense incurred.

Judge Buel was among the first who employed tiles in draining in the United States, being, he says, led to it by necessity, having no stone. He has laid some 10,000 feet of tiles, at an expense of about $15 per 1000 feet, and found them to answer an excellent purpose. Dr. J. J. Spencer, of Moorestown, New Jersey, has also drained a piece of low ground by means of tiles, and can now drive carts, plough and raise heavy crops of Indian corn, &c., where before there was a useless, unsightly, and unhealthy morass.

In general, under-drains may be dug no broader than is just necessary to afford room to work in, the sides being left straight or perpendicular. The ditch should be commenced at the lowest end or outlet, and opened up to higher ground. Where stones are employed either as a conduit at the bottom, or to form the drain of themselves, they should be broken to so small a size, that moles or ground-mice cannot penetrate among them, as they are very much inclined to do, opening holes through which the surface water enters, mixed with clay and earth, by which the interstices of the drain will be ultimately choked up. Judge Buel recommends the stone to be broken so as not to exceed 4 inch pieces. The expense of doing this, he says, will not be more than 25 or 30 cts. the cubic yard.

The use of draining tiles is evidently on the increase, and every improvement which is made in them naturally extends their field of usefulness; they are by far the most permanent and effective of all the materials used for draining land. Of draining bricks there are various shapes; the annexed figures represent a few of the most common, and the mode of placing them.

In fig. 1 and 1a, 84 bricks are required for every eight yards. In fig. 2, 55 bricks are required for every eight yards. In fig. 3, 110 bricks are required for every eight yards. Figs. 4 and 5 have been found very useful in the drainage of peat-bogs or quicksands. They are all, however, for most purposes inferior to the draining tile.

In the formation of drains, a shovel tapering to a point, and scoops of a peculiar shape, are commonly used. These are represented in the figures 6, 7, 8. The old-fashioned way of forming a drain is depicted in figures 9 and 10; in these the bottom of the drain was filled up partially with brushwood, stones, long ropes of twisted straw, others of ling or heath, which are much more tough and permanent. The expense of digging and filling in any of the above drains (exclusive of the brushwood or other materials) varies from 4s. 6d. to 5s. 6d. per score rods (120 yards local measure). The expense per acre will be, according to Mr. S. Taylor (Brit. Farm. Mag. vol. ii. p. 359),

DRAINING.

In many situations, where a spring is to be reached, it is very desirable to form a well by the side of the drain, according to the annexed outline. (Trans. High. Soc. vol. i. p. 223.) A very common modern mode of constructing the drain is according to the form in fig. 12. Loose mould or gravel is placed at the top to the depth of 1 foot. Sod, straw, heath, or rushes 4 inches; and then land stones 1 foot 8 inches thick surround the draining tiles.

The drain tiles, bricks, or other materials, are covered with any porous material that the locality affords. Stones, gravel, scoria, refuse of the foundries, ashes, peat, moss, sods, brushwood, straw, heath, ling, rushes, broken chalk, &c. (Trans. High. Soc. vol. vi. p. 89.) There are three very valuable papers on tile draining in this volume by Mr. Carmichael (p. 81), Mr. Stirling (p. 100), Mr. Wilson (p. 112); and on drainage, by Mr. Black (Ibid. vol. ii. p. 214); by Mr. Adam (p. 375), who considers the best sloped tile to be one similar to that of the Marquis of Tweeddale’s; by Mr. Dudgeon (Ibid. vol. ii. p. 71); by Mr. Macleod of Lockmore (Ibid. p. 103); on draining clay soils by Mr. Carmichael (Ibid. vol. iii. p. 34); on underground drainage (Quart. Journ. Agr. vol. vi. p. 232); on making drain tiles of peat (Ibid. vol. viii. p. 216) as a source of profitable outlay for capital (Ibid. vol. viii. p. 318, 540); on draining, and on the mole plough, by Mr. Aiton (Ibid. vol. ix. p. 388); on plug or clay draining, by Mr. Evans (Ibid. vol. iv. p. 501), and vol. ii. p. 68); on substituting tubes made of larch-wood for drain tiles in certain localities, by Mr. Scott (Trans. High. Soc. vol. xiii. p. 431, and Ibid. vol. xiv. p. 99). He estimates that these square tubes, having a clear waterway of 2 inches by 2½, made by the proprietor, having his own wood and sawmill, to be, for workmanship, about one penny per rood of 18 feet: they are pierced with auger holes in every part, and made in the following shapes, being fastened together with wooden pegs.

Mr. Wilson calculates the average expense with stones per rood to be 7s. 8d. (Quart. Journ. Agr. vol. i. p. 542.) Mr. Yule at per rood of 21 feet, 2 feet 9 inches deep with 3 inch tiles, at 1s. 6½; with 4 inches, 4½ to 5 feet deep, 1s. 3½; with 6 inch tiles, the same depth, 1s. 5½d. (Ibid. p. 397.)

The expense of tile draining has been thus estimated by Mr. Carmichael (Trans. High. Soc. vol. vi. p. 98) at per imperial acre; tiles being 2s. 6d. per 100, and soles 1s. 6d. per 100.

Brushwood and Straw Draining.—When tiles, stones, and other materials best adapted to the construction of drains cannot be procured, brush, straw, or even sod, has been employed to fill

*Ips. of stools. *St. drone.
DRAINING.

The bottom of under-drains. When brushwood is used, the trench may be dug from eighteen to twenty-four inches wide, and three or four feet deep. Saplings from two to six inches thick at the butt may be cut into lengths of four or five feet, and, commencing at the upper end of the ditch, placed diagonally or slantwise, the butts down and towards the outlet. When this is done the trench is apparently full. The brush is then all brought within the edges of the ditch, well trodden down, and the earth thrown in. Bundles of fagots are sometimes employed to lay at the bottom of the trench, and at other times large straw ropes. When the ground is marshy, coarse hay or straw should be put upon the bottom of the trench before laying the brush, and also upon the top of the brush after this is stamped down.

Wedge Draining is another method sometimes resorted to. The general mode of performing this is to form a narrow trench with a long, narrow shovel. The spout being taken out as deep as the shovel can go, a scoop is employed to cast into the mud and loose earth at the bottom. Then another shovel corresponding with the first is used, and a second spout is taken out, and then a narrower shovel still to clear the whole out, thus forming a trench with a ledge. A piece of sod, with the grass-side below, is then forced down, and, resting upon the ledge, a space is thus left for the water below. Sometimes the ledge is dispensed with, and the sod is merely formed into a wedge, narrowed towards the grassy side, and this, when the little trench is cleared out, is pressed into it and covered with earth; and, as it does not reach the narrow bottom, a channel remains below through which the water percolates. It is evident that where such under-drains can be constructed the bottom must be hard. This and the brush and straw drains are formed at comparatively little expense, and for a while operate very efficiently in conveying off the superfluous water. Still, as the materials are more or less perishable, and, moreover, liable to become closed up, they are an indifferent substitute for stone, and yet more so for the proper draining tile.

On the heavy clay soils, the drainage is sometimes effected by a drain or mole plough, which on some soils answers very well at a moderate expense. In this the plough draws a long tubular orifice in the clay by a heavy sharp-pointed rod instead of a share, which on some adhesive soils remains open, provided the fall for the water is sufficient, for years. It is, however, liable to too many casualties for general introduction. It is commonly worked either with a windlass or otherwise, by 18 or 20 horses drawing from strong whipkettles. (Brit. Husb. vol. i. p. 455.)

An excellent and improved imitation of the mole plough system is sometimes practised on heavy clay lands. A stout piece of rope or cable, four or five yards long, is laid at the bottom of the newly cut drain (one of the narrow wedge-formed drains); to the ends of this piece of rope is fastened a cross or T-headed piece of wood, by means of which it is drawn along the bottom of the drain after the clay and other materials have been filled over it; an arch or opening is thus left, similar to that formed by the mole plough; the expense in this case is merely that of digging and filling up the drain. (Brit. Farm. Mag. vol. ii. p. 367.)

In spite, however, of open and under-ground drainage, and of all that these and the boring system can effect, there are yet many thousands of acres in the east of England that, without the aid of the pump and the steam-engine, would still be covered with water. These were recommended many years since for this purpose by Mr. Savory, of Downham, (Comm. Board of Agr. vol. iv.) The gigantic powers of these great engines will be readily seen from the report of Mr. Glynn (Brit. Farm. Mag. vol. iii. p. 289.) Deeping Fen, near Spalding, containing 25,000 acres, is effectually drained by two steam-engines of 60 and 80 horse power. Littleport Fen, near Ely, of about 28,000 acres, is drained by two engines of 30 and 80 horse power. By this last engine, on July 18th, 1830, in a trial of eight hours, by the combustion of only 87 bushels of coals, 51,500 tons of water were raised. Windmills, for draining small engines, windmills were employed to a considerable extent. They were maintained, it is true, at a less expense, but the certain powers of the steam-engine have induced its general adoption. The carriage drain is an open, capacious drain, used very commonly in irrigation, and is usually made of wood, for the purpose of carrying the flood waters across ditches, hollow drains, &c.

DRAINING-PLoughs. Such ploughs as are contrived for the purpose of cutting drains, in order to carry off the water from wet soils. See PLoughs.

DRANK, or DRAUK. A very common name in many parts of England for a barrel; but is properly only the provincial name for the scaly brone-grass, cheat, or chess.

DRENCH. In farriery, a large drink or draught of any liquid remedy given to an animal, usually by means of a horn properly cut for the purpose. A very able paper on drenching horses, by Mr. John Stewart, veterinary surgeon, is in the Quart. Journ. of Agr. vol. x. p. 656, which may be consulted with advantage. A drink is not so portable as a boll; it is more troublesome to give, and a portion of it is usually wasted. (The Horse, p. 392.) Mr. Stewart strenuously urges the following propositions: 1. That draughts, particularly when pungent or disagreeable, are dangerous. 2. That by no care can the danger be altogether avoided. 3. That no draught should be given unless the horse be in danger of dying without it. 4. That the safest way of administering draughts is to give them when the horse is lying. 5. That a draught is seldom or never absolutely necessary but in diseases which make the horse lie. 6. That a bottle is a better drenching instrument than a horn.

DRESSING. Any sort of manure applied to land for the purpose of its improvement. Top-dressing is that sort of fertilizer which is spread over or applied upon the surface of the land, either when the crop is upon the ground or not.

DRILL. A small track or longitudinal opening in the form of a slight furrow, made in
DRILL-HUSBANDRY.

The practice of sowing or planting grain and other seeds or roots with a machine, in regular rows or drills, in place of scattering them by hand, by which means they are spread at more equal distances, and lodged at better depths, than can be done in the latter way. "Of our modern improvements," says Dr. Fothergill (Com. Board of Agr. vol. iv, p. 156), "the introduction of drill-husbandry has generally allowed to be the most important." Horse-hoeing is intimately connected with it, and for the most part forms part of the same system.

DRILLING. The act of putting different kinds of crops into the ground in the drill-method. Mr. Bramston gives the result of an experiment on the comparative advantages of narrow and wide drilling. (Journ. of Roy. Eng. Agr. Soc. vol. i, p. 294.)

DRILL-MACHINES. Implements for distributing seed and manure easily, and at regular distances. A rude kind of drill has been used in agriculture from a very remote period. The cultivators of China, Japan, Arabia, and the Carnatic, have drilled and dibbled in their seed from time immemorial. (The Chinese drill, or drill-plough, is noticed Quart. Journ. of Agr. vol. i, p. 675.) After the Hindoos have thus deposited their seed, they use a kind of subsoil plough, which passes under and loosens the soil to the depth of about eight inches three drills' breadth at a time. (Com. Board of Agr. vi. 355.) Gabriel Platte, in 1638-1653, describes a rude dibbling machine formed of iron pins, "made to play up and down like Virginal jacks;" and John Worlidge, in his Husbandry, published in 1669, not only advocated the use of the seed drill, but of the manure drill. Evelyn, in the same year (Trans. Roy. Soc. vol. v. p. 1056), mentions with much commendation a drill-plough which had been invented in Germany, whence it had found its way into Spain, and had been noticed by the Earl of Sandwich, the English ambassador, who forwarded it to England as the invention of a Don Leucailla. Jethro Tull at a later period (1730-40), devoted all his energies to promote the introduction of this machine, more especially as it admitted the use of the horse-hoe. The united advantages of these excited in him the highest enthusiasm. But it is to be observed, a drill had been gradually improved by the labour of succeeding mechanists, that this invaluable machine, principally through the exertions of Lord Leicester and others, became generally used in England. Thence it appears that the method of sowing corn and other seeds by machines in England is not (as is well remarked by Mr. J. A. Ransome, the eminent agricultural machinemaker of Ipswich, to whom I am indebted for almost the whole of this article), a modern idea, though the machines have been so much improved within the last century as to make them bear but little resemblance to those formerly in use.

Passing by those of more ancient date, we come to the inventions of Jethro Tull, for the purpose of carrying out his system of drill-husbandry, about 1733. His first invention was a drill-plough to sow wheat and turnip seed in drills, three rows at a time. There were two boxes for the seed, and these, with the coulters, were placed one set behind the other, so that two sorts of seed might be sown at the same time. A harrow to cover in the seed was attached behind.

Jethro Tull also invented a turnip-drill somewhat similar to the other in general arrangement, but of lighter construction. The feeding spout was so arranged as to carry one half of the seed backwards after the earth had fallen into the channel; a harrow was pinned to the beam; and by this arrangement one half of the seed would spring up sooner than the other, and so part of it escape the turnip fly. When desirable to turn the machine, the harrow was to be lifted and the feeding would stop. The manner of delivering the seeds to the funnels in both the above drills was by notched barrels, and Tull was the first who used cavities in the surfaces of solid cylinders for the feeding. Nothing material in the history of the drill occurred afterwards till 1782, but little progress appears to have been made to that period in drill-husbandry.

About this time Sir John Anstruther, near Edinburgh, presented the model of an improved drill-plough of his own invention to the Bath and West of England Society, having had one in use for eight years previous without its getting out of order. It was a double drill-plough of simple construction, by which two furrows could be sown at a time, the horse walking between them, and by this means the injury usually done by the horse's feet to the fine ground was avoided. Within the next ten years twelve patents were taken out for drill-machines, two of which were for depositing manure with the seed; but the most approved appear to have been those invented by James Cooke, a clergymen of Heaton Norris, in Lancashire; and the general principles of these machines, from their simplicity, have been adopted in the construction of some of the most approved of the present day.

For a cut of Cooke's grain-drill, see Pl. 14, fig. 1.

The seed-box of Cooke's drill, is of a peculiar shape, the hinder part extending lower than the fore part. It is divided by partitions, and so supported by adjustable bearings as to preserve a regular delivery of the seed whilst the machine is passing over uneven ground. The feeding cylinder is made to revolve by a tooth-wheel, which is fixed on each end of the main axle, and gears with other toothed wheels on each end of the cylinder; the surface of the cylinder is furnished with a series of cups which revolve therewith, and are of various sizes, according to the different seeds. These deposit the seed regularly in funnels, the lower ends of which lead immediately behind the coulters, which are so connected by a beam, so as to be kept in an even line, and are capable of being held out of working when desired by a hook and link in the centre. The seed, as it is deposited, is covered in by a harrow fixed behind. The carriage wheels are larger in size.
than usual, by which means the machine is more easily drawn over uneven ground; and the labour of working is reduced.

"Of corn drills," says Loudon, "Cooke's improved drill and horse-hoe, though not the most fashionable, is one of the most useful implements of this kind on light dry soils, on even surfaces, and in dry climates. It has been much used in Norfolk and Suffolk, and many other parts of England. The advantage of this machine are said to consist,—1. In the wheels being so large that the machine can travel on any road without trouble or danger of breaking; also from the farm to the field, &c., without taking to pieces. 2. In the coulter-beam (o), with all the coulters moving with great ease, on the principle of the pentagraph, to the right or left, so as to counteract the irregularity of the horses' draught, by which means the drills may be made straight; and, where lands or ridges are made four and a half, or nine and a half feet wide, the horse may always go in the furrow, without setting a foot on the land, either in drilling or horse-hoeing. 3. In the seed supplying itself regularly, without any attention, from the upper to the lower boxes, as it is distributed. 4. In lifting the pin on the coulter-beam to a hook on the axis of the wheels, by which means the coulters are kept out of the ground, at the end of the land, without the least labour or fatigue to the person who attends the machine. 5. In going up or down steep hills, in the seed-box being elevated or depressed accordingly, so as to render the distribution of the seed regular; and the seed being covered by a lid, and thus screened from wind or rain. The same machine is easily transformed into a cultivator, horse-hoe, scarifier, or grubber, all which operations it performs exceedingly well; and by substituting a corn-rake, stubble-rake, or quitch-rake, for the beam of coulters, or hoe (o), it will rake corn-stubbles, or clean lands of root weeds. When corn is to be sown in rows, and the intervals between them are so small as to scarcely allow a man to stand, a machine superior to this one; and from being long in a course of manufacture, few can be made so cheap.

But these advantages, though considerable in the process of drilling, are nothing, when compared with those which arise from the use of the horse-hoe; with which from 8 to 10 acres of land may be hoed in one day, with one man, a boy, and one horse, at a trifling expense, in a style far superior to, and more effectual than, any hand-hoeing whatever; also at times and seasons when it is impossible for the hand-hoe to be used at all. Pl. 14, fig. 2.

"The Norfolk drill, or improved lever drill, is a corn drill on a larger scale than Cooke's, as it sows a breadth of nine feet at once: it is chiefly used in the light soils of Norfolk and Suffolk as being more expeditious than Cooke's, but it also costs about double the sum.

"Morton's improved grain drill-machine is decidedly the simplest and best of corn drills. In this machine three hoppers are included in one box, the seed escaping out of all the three by the revolution of three seed cylinders upon one axis, and the handles of different lengths are produced simply by the shifting of a nut, that fixes a screw moving in a groove in the under-frame, by which the distance between the two outside conductors and the central one (which is fixed) can be varied from 9 to 10 or 11 inches; and that the two small wheels may always be at the same distances respectively as the conductors, there are two washers (hollow cylinders), an inch in breadth, on the axle-arms of each, which may be transferred either to the three sides of the wheels, so as to make their distances from the outside conductors 9, 10, or 11 inches respectively also. The small wheels may be raised or depressed, so as to alter the depth at which the seed shall be deposited, by the action of a wedge, which retains the upright part of the axe in any one of a number of notches, which are made similarly in both, and which are caught by an iron plate on the upper side of the arms which carry the axles. This machine may be still further improved by increasing the number of conductors to five instead of three; the latter number giving too light work to the horses." (Highland Soc. Trans. vol. vii.)

About the year 1790, Henry Baldwin of Mendham, near Harleston in Norfolk, a farmer, aided by an ingenious workman named Samuel Wells, then in his employment, improved upon the drill known as Cooke's drill, which by this time was in use in several parts of Norfolk. The improvement consisted,—first, in making a sliding axletree, by which the carriage wheel could be extended at pleasure to the width of the "stitches" or lands, and by which means another box with cups and more coulters could be used. Thus a drill containing 14 coulters could be enlarged to one of 18 or 20. Second, in making self-regulating levers, to which the coulters were attached; this was done by hanging each coulter on a distinct lever, placed at right angles with the cross bar of the framing, upon which each lever was made to swing by an ordinary hinge joint, and had a movable weight at its opposite end, to press the coulter into the soil; and, the several levers being made to work independently of each other, they accommodated themselves to the irregularity of the surface of the land, and the impediments which they might meet, without disturbing the whole. The above were two very important improvements; and they are both in use in England, to this day.

Suffolk Corn and Manure Drill.—Following the improvements just referred to, are those by James Smyth of Peasenhall, and his brother Jonathan Smyth of Sweffling, who have been engaged in the manufacture upwards of 40 years, the chief summary of which is as follows:—1. A mode of adjusting the coulter to distances apart from each other, from four and a half inches and upwards. 2. An improved manure-box and cups, for the delivery of manure with the grain. 3. A plan to drill in manure and grain, and sow small seeds at the same time. 4. The swing steerage, by which means the man attending the drill can move the coulters to the right or to the left hand, so as to keep the straight and parallel lines for sowing the seeds. 5. Various improvements in gearing, clamping wheels, barrel, &c. An engraving taken from one of Smyth's most perfect grain and manure drills is given in
Plate 14, fig. 3, by the description we have given of Cooke's and of the subsequent improvements by Baldwin, Wells, and Smyth, the plan will be fully understood.

The Suffolk grain and manure drill may also be arranged for sowing turnips and manure at the same time. In such cases the cord-box has to be exchanged for a double one, in one part of which runs a spindle with brushes, where the turnip-seed is contained. There are small copper slides, with different numbers, from one to six holes pierced in them, through which the seed is delivered as required. The other part of the box contains the manure, which is thrown into the funnels, and these are so arranged that it drops into the earth just before the seed.

Morton’s improved grain drill, is spoken of in the Highland Society’s Transactions, (vol. vii.) as decidedly the simplest and best of grain drills. A description and cut of this machine which drills 3 rows, is given in Loud. Encyc. of Agr., p. 409.

Hornsby’s Patent Drop Drill is intended for drills in seed with narrow at intervals, but the construction of it is very different from the Suffolk. In this, the manner of regulating the delivery is by having a coulter of a peculiar form inside, in which a circular box revolves on an axle which passes through one side thereof. This box is divided into compartments closed by small doors, which are kept shut by a spring to each; the compartments in the box are supplied through a series of funnels, the end of the lower one entering one side of the box below the centre.

On the machine being moved forwards, this box revolves by means of appropriate cog-wheels; and as each spring arrives at the ground, the door to which it is attached opens, and the contents of that compartment are deposited, to be again replaced, when it arrives at the part of its rotation at the end of the funnel, and so on successively.

Graunsell’s Patent Drop Drill.—This drill is for the purpose of depositing corn, grain, pulse, and manure at intervals, the distances of which may be regulated at pleasure. (Pl. 14, fig. 4.) To each of the four coulter以前 mentioned a circular iron ring is fixed about midway between the nave and rim of the drill carriage-wheel. In this there is a number of holes to carry a series of studs, which may be varied according to circumstances; and as these studs come in succession, when the wheel turns they open valves for the delivery of the seed and manure, which close again immediately the stud has passed. A further improvement is by the adoption of projecting arms or shovels, to draw the manure and grain to the funnels, instead of taking the same up in cups in the way adopted in other drills.

The Messrs. Ransome give the following sketch of the chief modern improvements made in the drill, which have greatly added to its usefulness, without having increased its cost.

The drills usually made by the best makers in England, are of several kinds; but their description may be briefly comprehended under three or four heads.

1. The Common Lever Drill. This invaluable machine, which is the one in the most general use, is adapted for drilling grain, on either level grounds or ridges, and on all descriptions of soil. These are, as we have stated in our previous description, furnished with independent levers, by which the coulters are each readily and separately made to avoid any rocks or irregularities of the ground, and a “press steelyard,” to force the coulter, in case of need, into hard ground, with a varying degree of pressure, according to the texture of the soil.

These coulters can now be set so as to drill the corn at any width, from 4 inches to a

machine, which is the one in the most general use, is adapted for drilling grain, on either level grounds or ridges, and on all descriptions of soil. These are, as we have stated in our previous description, furnished with independent levers, by which the coulters are each readily and separately made to avoid any rocks or irregularities of the ground, and a “press steelyard,” to force the coulter, in case of need, into hard ground, with a varying degree of pressure, according to the texture of the soil.

These coulters can now be set so as to drill the corn at any width, from 4 inches to a

2. The next description of drill to which I shall allude, is The Manure Drill. This drill is formed very readily, by merely adding to the common corn drill, an operation which any husbandman can perform, “a manure box.” It is a simple yet accurately working apparatus for delivering the manure, which, in the best drills, does with great evenness, and in quantities varying as “the slip” is placed, from 6 to 8 bushels per acre. In the best drills, also, a very important improvement has been made within the last few years, which consists in the use of separate coulters for manure and seed. The manure is now deposited according to the mode preferred by the cultivator, not only from 2 to 3 inches in the ground than the seed, but from 10 to 12 inches in ad
vance of it, so as to give the soil time to cover the manure before the next coulters deposit the seed;—whereas, on the old plan of depositing the seed and the fertilizer together down one pipe, an evil was liable to arise when it was used with some of the more powerful artificial manures; the seed and the manure were too close together, and the manure was not always dropped in what is commonly its best position, under the seed.

3. The third variety of drill which I shall notice, is the Northumberland Frame Manure and Turnip Ridging Drill. This excellent drill is furnished with pressing rollers (one to each coulter), which form the land into ridges—and precede the coulters. These deliver in separate coulters, 1st, the manure; and 2dly, the seed; and the drill is provided with a second roller, which follows the coulters and closes the rows. This machine drills two rows at a time—weights only about 1 cwt. and one man and a horse can easily drill from 8 to 10 acres per day.

Besides these three most commonly used drills, there are several others—such as the Two Coulters Sheep manure Lever Drill; this has a swing steerate, to which we have before alluded, and a slipp axle-tree to vary the distances of the ridges—(for this valuable implement a prize was awarded to Mr. Garret at the Cambridge meeting). To this a set of hoes is occasionally attached, furnished with independent levers either for ridge-work or otherwise.

There are in England many other varieties of drills, but they involve no particularly useful principles, if we except the drop drills, the chief object of which is to save the quantity of manure. In these the seed or corn is mixed, and deposited with the manure.

From this brief enumeration the farmer will see that the modern drill-makers have not neglected their duty, in the adoption of every improvement calculated to simplify and render more serviceable the common and the manure drill; and I am highly gratified to be able to add, that there is now every prospect of their skill and enterprise being rewarded by the cultivators of our country; for I find, from an eminent maker, that the demand for manure drills has within the last two years been greater than ever was remembered before.

The chief advantages of the use of the drill, are the regular deposition of the seed at a uniform regulated depth, from which arises a considerable saving of seed (at least one-third)—and the facility afforded in cleaning the land either by the hand or horse-hoe. The importance of these results is, happily for our country, rapidly becoming generally understood: and the result of experiments which I witnessed to a considerable extent, upon some of the poorest gravelly soils of Surrey, by Mr. Hewitt Davis and others, convince me that, by the use of this machine, combined with careful hoeing and weeding the crops, a saving even of half the usual quantity of seed now used by the drill may be effected. And again, I cannot too often urge upon the farmer of the upland soils, far away from supplies of manure, the use of the manure drill, and those fertilizers expressly prepared for its use; since by these one ton of manure is sufficient for three acres. And let the farmer remember, that it is not only the first cost of all manures which makes them expensive, but the comparative labour saved in their application, which must also be taken into the account when the cultivator is estimating their value. And further, let him remember that the best and richest farm compost is likely to convey to his fields a multitude of weeds, the cost of whose removal too rarely forms a portion of such comparative estimates.

The patents which have been taken out in England, during the last half century, for drill ploughs and improvements in sowing machines form a long list.

The advantages derived from using drill machines for sowing wheat and the other small grains have been summed up by Mr. Binns, at a meeting of an English agricultural society, as follows:

1. The seed is delivered with regularity.
2. It is deposited at proper depth.
3. The weeds, during the growth of plants, are destroyed with great facility.
4. The plants cultivated receive the undivided benefit of the soil and manure, and have not to maintain a constant struggle with weeds.
5. The land by the process of hoeing, is undergoing preparations for another crop.
6. The necessity of summer fallowing is avoided.
7. By admission of the sun and air between the rows, a stronger and healthier plant is produced, and of course a heavier crop.
8. By stirring the soil it is more susceptible of benefit from the atmosphere, imbibing more oxygen, and being both warmed and enriched by the sun.
10. By drilling, the farmer is enabled to have heavier crops of beans and wheat on light land.
11. Clover and grass-seeds answer incomparably better in the pulverization produced by hoeing, independent of the clearness from weeds.
12. The drills give facility for depositing smaller portions of manure with greater effect.

"These advantages," says the editor of the Cultivator, "are all self-evident to a good farmer; and it might have been added, as a thirteenth advantage, that drilling economizes seed, though Mr. Binns rejects it, on the ground that, if the plants are thin, they throw out side-shoots, which produce imperfect grain, and ripen unequally. In drill husbandry, Mr. Binns affirms, fifty-six bushels of wheat per acre have been raised on the light soils of Norfolk."

It is believed by some that the plan of sowing wheat by drill machines is a refinement in agriculture which cannot be profitably adopted in the United States, where the price of grain is of late years much lower than in England. The introduction of the practice will perhaps be slow, but there cannot, we think, be a doubt of its final general adoption in all the best cultivated wheat-growing districts. The first expense of the machine is doubtless the princi
The admirable drill for sowing wheat has been invented and patented by Moses Pennock and son Samuel, of Kennett Square, Chester county, Pennsylvania. (See Plate 14, fig. 5.)

It has been used for several years in the southern parts of Pennsylvania and adjoining states, and the greatest satisfaction has been expressed for its performance.

Pennock's drill is capable of sowing 8 acres of wheat, or planting 15 acres of Indian corn, per day. The wheat is placed in boxes, connecting with sowing tubes which penetrate into the ground, scattering it in rows 9 inches apart, and covering about an average depth of 2¼ inches. If one or more of the tubes comes in contact with a stone, root, or other obstacle beneath the surface, a small chain to which it is attached breaks a wooden peg, and thus saves the machine from any serious injury, the detention being only a few seconds when pegs are kept in order. The preparation of the ground is similar to that adopted in the broad-cast method. The machine is driven with great ease by one horse, and requires but one attendant, in sowing wheat. For every bushel sown by hand in the ordinary way, the drill saves from 8 to 12 quarts. The machine is easily managed and not liable to get out of order. Besides covering the wheat much more effectually than can be done by the harrow, it raises ridges about 3 inches high on each side of the tube. These ridges crumble down, and by the action of the frost and rains, and thus cover the young plants and prevent them from being thrown out during the freezing and thawing of the ground and killed, as so commonly occurs in the winters of the United States. Samuel Pennock, the junior inventor, has for several years been using the drill extensively in putting in crops. His usual charge, for the use of a machine, including the horse and his own services, is $4 per day, or 50 cents per acre. When the wheat sells for $1.55 or $1.50 per bushel, the seed saved will pay all the expense of drilling, (especially when the farmer owns the drill), the crop being placed in a far better condition than can be effected by the broad-cast method, as will be evident from a consideration of the various advantages enumerated, and these constitute the chief profit.

When the machine is used for planting Indian corn, (for which purpose it is singularly well adapted), some of the levers are thrown out of gear, leaving the remainder so arranged as to strike out two rows, 4½ feet apart, in which the corn is dropped at regular distances and covered with about 3½ inches of earth, or less if desired. It may be afterwards thinned, but must of course be always tilled in one direction. The ground is flushed and harrowed, after which rows 9 feet apart are run with a plough and one horse, in which row the corn is drawn by the drill walks in going and returning. In this way about 15 acres of Indian corn may be planted in a day, and thus a considerable saving of labour is effected by the owner of a drill, since to plant the same number of acres by hand, in the usual way, would require 5 hands equal to fifteen days work, with the addition of a second plough to run out furrows, and two droppers. Although Pennock's drill costs $100, it seems evident that the saving of labour in planting the corn crop will more than pay the interest and wear and tear of the machine, leaving none of these charges to be placed against the wheat crop.

Persons who have watched the progress of corn crops planted by the drill, and compared the results with those of crops planted by hand, say, that under ordinary circumstances, a gain of 5 bushels per acre may be fairly credited to the drilled corn. Some even go so far as to say that drilling has added one-fourth to the crop. The deep covering is regarded, where the soil is perfectly dry, and of a light texture, as a very great advantage. The corn will at first appear backward, but is soon observed to catch up and outstrip that which has been covered more superficially. It is also placed so more out of the reach of birds, and escapes injury from the cut-worm, and heart-worm, or, as it is also called, bud worm. The cut-worm usually commits its depredations by night, taking off the plants at, or very near, the surface of the ground, whilst by day it cuts a little below the surface. Now, when corn is deeply covered it admits of being topped, without being entirely killed, and suffers little further injury than retardation.

Pennock's drill, besides sowing beans, peas, and all kinds of round seeds, including rutabaga, is, like Cooke's English drill, capable of being adapted to the purposes of a horse-hoe, cultivator, extirpator, and harrow, by the adjustment of hoes, harrow-teeth, &c. Besides the approbation bestowed on Pennock's drill by individual farmers, for some of whom they have sown as much as 100 acres a season, several public institutions have awarded premiums to the inventors, among which we may mention the Philadelphia Agricultural Society, Franklin Institute of Pennsylvania, and American Institute of New York.

It would be a desideratum in the United States to have drills like those used in England, adapted to sowing seeds and sprinkling with them at the same time some of the concentrated manures, such as bone-dust, poudrette, &c. But this again, like every other addition, must increase the cost, already so great an obstacle.

As yet the drill system in the United States has been principally confined to sowing turnips and beets, and sometimes Indian corn. The results with those who have had good implements and known how to use them, has been a conviction of their utility and economy, especially where the root culture has been extensively carried on. One-rowed drills are almost the only kind to be met with in the warehouses where agricultural implements are kept for sale.

Drill-barrows are implements furnished with handles, similar to those of a wheel-barrow, and designed to be propelled by hand. Among these Willits's Latest Improved Seeders is said to be the best, as it puts the seed into the ground with regularity and in the best manner.
It opens the furrow, drops the seed, covers and rolls them down. It will sow almost any kind of garden seeds, such as beets, rutabaga, mangel-wurzel, carrots, turnips, parsnips, onions, &c., and costs $1.50.

Euckenborough's Seed-planter is of simple construction, and has been found to answer well for planting corn, sugar-beet, &c. It deposits the seed either in drill-rows or hills, as may be desired. When the ground is properly prepared, a man, with one horse, it is said, can furrow out, drop, cover, and press down the seed on an acre of ground in one hour, or 10 acres in a day. The seed is covered by falling into the furrow of the soil, which is fine and pulverized by the plow of the cultivator teeth. The machine will bury the seed 3 inches deep, if desired—one inch being the general rule for Indian corn, and only one-fourth of an inch for turnips. By simply turning a screw one way or the other the depth is regulated.

Steam's Improved Turnip Drill, which is a modification of the English Northumberland Drill, enjoys a good reputation. It sows beets, peas, and, generally, all kinds of round or oval-shaped seeds.

Commercial's Drill Barrow, is said to perform well, and is recommended by its simplicity of construction and cheapness. By multiplying the wheels, or rather by uniting several machines, it may be adapted to horse power, and thus applied to field culture for sugar-beets, rutabagas, &c., and, even, it is said, for wheat and other small grains.

DRILL-ROLLER. A roller so contrived as to form regular small incisions or drills in the ground at proper depths for the seed. It is merely a common cylinder roller, generally of iron, about seven feet long, around which are put cutting-wheels of cast iron, each of which generally weighs about a ton. The cutting wheels, being movable, may be fixed at any distance, by means of washers.

DROPSY. In farriery, a disease incident to horses, and sometimes called water-farcy. See Horses and Sheep, Diseases of.

DROPWORT, WATER (Ethaneth). Smith (Eng. Flor. vol. ii. p. 68), describes five species in England. The common water-dropwort; the pearly water-dropwort; the smooth-wort water-dropwort; the fine-leaved water-dropwort; and the hemlock water-dropwort. They are aquatic herbs, perennial, and biennials; fetid, and often poisonous; found in ditches, ponds, and other watery places. The first three species are not reckoned poisonous; but the last (Ethaneth crocata), is perhaps, in its fresh state, the most virulent of British plants. Brood mares, according to Sir Thomas Frankland, sometimes eat the root, and are poisoned by it. The root consists of many fleshy knobs, resembling parsnips externally, abounding with an orange-coloured, fetid, and very poisonous juice, such as exudes less plentifully from all parts of the herb when wounded. The stem is from two to five feet high, much branch-ed, somewhat forked, and hollow. The leaves are of a dark shining green, and doubly pinnate. The flowers are white, or tinged with purple, very numerous and crowded.

Two or three species of cowbane are enu-merated in the United States, where the plant is believed to be an active poison, particularly to horned cattle, when eaten by them; for which reason it should be eradicated from all pastures where it is discovered. (Darlington's Flor. Cox.)

DROSOMETER (from the Greek). An instrument constructed for measuring the quantity of dew that collects on the surface of a body exposed to the open air during the night. The first instrument for this purpose was proposed by Weidler. It consisted of a bent balance which marked in grains the preponderance which a piece of glass of certain dimensions, laid horizontally in one of the scales had acquired from the settling and adhesion of the globules of moisture. A simpler and more convenient drosometer would be formed on the principle of the rain gauge; and in order to facilitate the descent of the dew down the sides of the funnel into the tube, a coat of deliqueu salt of tartar may be spread over the shallow surface. Dr. Wells, in making his celebrated experiments on dew, exposed a small quantity of wool to the open sky, and the difference in its weight when laid down and taken up showed the quantity of moisture it had imbibed in the interval. (Erard's Dict. of Science.)

DROUGHT. The effect of long-continued dry weather, or the want of rain: when applied to animals, it signifies thirst, or want of drink.

DRUDGE. An implement of the rake or harrow kind, peculiar to West Devonshire. It is a sort of long heavy wooden-toothed rake, the teeth being broad, and placed with the wide or flat side foremost. It is drawn by horses or oxen, and made use of, in paring and burning operations, to collect the broken parts or fragments of the sward which have been loosened by the operation of the plough and harrow.

DRY ROT. The name of a disease which attacks wood, rendering it pulverulent by destroying the cohesion of its parts. It frequently depends on fungous plants, which are nourished upon the sap in the wood, and by taking that away destroy the cohesive property of the woody particles. The fungi most destructive are the Merninus lacrymans, the Poly- porous destructor, and several species of Sporo-trichum. The production of these fungi is favoured by whatever causes the sap remaining in the wood to ferment; as, for example, defect of ventilation. In the old cathedrals and other public edifices, the dry rot never appeared, because care was taken to ventilate the beams. It occurs among the timbers of ships, where it sometimes commits the most serious damage and in damp ill-ventilated houses. Mr. Batson, in the Trans. of Soc. for Encour. of Arts, recommended charring as a preventative. Some excellent advice is also given on this subject in a paper by Mr. Hart, “On the Cause of Dry Rot in the Larch and other Trees” (Trans. High. Soc. vol. iv. p. 395). The process which has been patented by Mr. Kyan, namely, steeping the wood for a week or two in a strong solution of corrosive sublimate, which coagulates the albumen of the wood, and destroys the
DUCK.

fungus, appears to be the best preventative at present known. Sir W. Burnet has recently invented another process for rendering wood, cordage, and all descriptions of woolen, free from the effects of dry rot, which has lately been tested and found very efficacious by government. I understand the active matter in Sir William Burnet’s solution is sulphate of copper. (Willich’s Dom. Ency.)

DUCK. (Dutch Duck, to dip; Lat. anas.)

There are many varieties of ducks described by naturalists, but only two are to be found in our farm-yards; namely, the common duck and the Muscovy duck, the latter is a useful and economical bird, requiring little care. It is perfectly independent, if there is only a pond or mud hole to dabble in; for moisture is its element, and it cannot thrive without it. One drake is sufficient for eight or ten ducks. Duck hovels should be kept very clean and warm, with a row of boxes inside to induce the duck to lay her eggs in them; otherwise in the laying season she drops her egg in the water, or on the bare ground, or seeks by-places, where the eye of the vigilant housewife cannot penetrate. For this reason, it is better not to let them out very early in the morning during the laying months, which are March, April, and May. Their hovel should be well secured from the entrance of foxes, polecats, weasels, &c., and it should be defended from wind and weather. Ducks “feed themselves” a great part of the year, as they are gross eaters; loving every sort of garbage, such as offal, earthworms, caterpillars, sweepings of barns, residue of breweries, sludges, spiders, and insects. In this particular, they are admirable gardeners, effecting more in one night than two gardeners could perform in a week towards clearing a garden of slugs, snails, and caterpillars. The waters which ducks frequent should contain no leeches. If a pond has any leeches in it, put in a few trench, which will soon devour them. The herb hemblane should also be carefully rooted up from the neighbourhood of ducks and poultry in general, from its poisonous qualities. A duck lays from 50 to 60 eggs, but the common duck is a useful and economical bird, requiring little care. The young ducklings are hatched in a month, and then the mother should be put in a coop for some time, or she will carry her brood immediately to the water, and tire them; besides which, many perish with cold. They should be allowed to get strong first. Many housewives prefer setting duck eggs under hens and hen turkeys, in order to prevent this; but if the duck is secured, the end is answered. Let the ducklings have dabbles of water near the coop to dabble in, and feed them when out of the egg-shell with bread crumbled in milk, for a few days. Nettle-leaves boiled tender and chopped very small, made into a paste with barley meal, is a warm, wholesome food. When the ducklings gain strength, give them plenty of raw potherbs well chopped, mixed with soaked bran, barley, mashed potatoes, mashed acorns, or fish, if near the coast. Ducklings intended for the table should not be allowed to swim about much; it keeps them lean. Early ducks are valuable. They should be confined to their hovel or to a coop during the process of fattening, and fed there for one month upon oats and water in clean troughs. It is of no use giving them many oats: they will no more fatten upon musky oats than we can thrive upon musky bread. Do not try to fatten them either upon garbage. It gives the flesh a bad taste. Boiled rice is a nice delicate variety of food. The fine, white Aylesbury breed are the most profitable and the handsomest duck. They are also the earliest in laying and setting. I will give a recipe for salting ducks, as they are done by the great butcher is economical and excellent food. Two days after the well-fatted ducks are killed, cut them open at the inferior part, and draw away the thighs, wings, and flesh of the stomach and rump. Put the whole, with the neck and tip of the rump in a tub of salt, with a little nitre and a few bay leaves mixed in it, to give the flesh a fine red colour. Cover it up in the salt a fortnight; then cut the fowl in four quarters, lard it with cloves, and put it into a pot or pots, with some spice. Duck feathers are very profitable, and, mixed with those of the goose, make good pillows, &c. The feathers should be plucked in May and September, while the duck is yet warm after death. Dry the feathers in bags in the oven after the bread has been withdrawn, and repeat the process several times. See FEATHERS.

DUCK, THE MUSCOVY (Anas Moschata), a native of South America, is a gaudy-looking large bird, often introduced into our farm-yards, but not much approved; more for show than use. Their flesh is not so good to eat as that of the common duck, and the drake is very tyrannical in attacking the poultry, and causing an uproar in the peaceful homestead, besides spoiling a superior breed.

DUCK, THE WILD (Anas boschas, Linn.), is rather less in size than the tame duck, but differs little in plumage; it weighs usually about 2½ lbs., but has been known to reach 3½. In-shore shooting of wild ducks is considered to be legitimate sporting about the middle of August, when the flappers, or young ducks, have begun to take wing. The last Game Act in England has a clause to prevent wild-fowl being killed from the last day of March to the 1st of October, and this applies equally to shooting and taking them in decoys. The wild ducks pair in the spring, build their nest among rushes near water, and lay from 10 to 16 eggs. (Willich’s Dom. Ency.) For descriptions of the numerous species of the wild duck found in the United States, see Nutall’s Ornithology of Water Birds.
DUCK'S FOOT (Podophyllum; abridged from anapodophyllum, a word signifying a duck's foot, as the leaves bear some resemblance to it). This plant requires a moist, shady situation, and to be grown in the soil; increased by division at the root. (Paxton's Bot. Dict.)

DUCKWEED (Lemna). A genus of minute, herbaceous, floating plants, consisting of four species, all of which are natives of England, and grow abundantly in ponds, ditches, and stagnant waters. They are in flower from June to August. Duckweed is a small green herb, consisting of little roundish leaf-like disks. It is not, perhaps, generally known that duckweed, if allowed to spread itself over ponds and swards, in which fish are preserved, will ultimately destroy them, by its forming a compact mat upon the surface, thereby preventing the fish, when they rise to the surface of the water for air, from breathing. It should on this account be abstracted diligently with a rake, or some such implement, and kept under before it attains an ascendancy, which it will do in a very short time if not seasonably withdrawn. The quantities of fish that perish under the influence of this weed are incalculable. Ducks feed upon the "lema" with surprising avidity, and thence it derives its name (duck's meat or duckweed). Ducks, by dabbling and gouring in foul pools, where it predominates, and its adhering to their feathers, are in the habit of introducing it into other waters, where it never appeared before. (Eng. Flora, vol. i. p. 31; Willich's Dom. Ency.)

DUN (Sax. dun). A colour partaking of brown and black, frequent in horses.

DUNES (Ang.-Sax. low hills). Hills of movable sand, which are met with along the sea coast in various parts of Great Britain, Ireland, and the Continent. (Bronte's Dict. of Science.)

DUNG and DUNGHILL. See Farm-yard and Compost.

DURHAM CATTLE. See Cattle.

DUST BRAND. One of the local names for the smut in wheat.

DUTCH ASHES. See Ashes.

DUTCH ELM (Ulnus subtorta). See Elm.

DWARF BAY. See Mezerion.

DWARF ROSE BAY. See Mountain Laurel.

DWARF BERRIES. See Nightshade.

DWARF OAK. A shrub, sometimes employed for making live fences. It grows very fast, and becomes thick by cutting very rapidly.

DYKE (Sax. die; Erse, dyk). A sort of wall or mound formed of earth or turfs. In Scotland it is applied to any wall round a field.

DYRES. DYNAMOMETER (Gr. dynamic, power, and metron, measure). An instrument for measuring power of any kind, as the strength of men and animals, the force of machinery, &c. Some interesting results relating to the average strength of men at different ages, and of different weights and sizes, have been produced by M. Quetelet of Brussels, from numerous experiments with Regnier's dynamometer, one of the most convenient that is made. It consists of two flat plates of steel of a curved form, increasing in thickness towards the ends, which unite into solid cylindrical loops; the curved sides of the plates being placed opposite to each other, and the whole forming an entire elliptic spring. On the application of this instrument as a link in the line of draught, the oval becomes lengthened in proportion to the degree of force acting on the loops in opposite directions, and the curved sides approach more nearly towards each other accordingly. The degree of approximation in the plates is shown on the scale, in divisions corresponding to half and whole hundred weights, by means of a cross rod secured to one plate acting on a crank attached to the opposite one, thus communicating its effect to the lever index, which, moving over the divisions of the scale, marks the varying degree of force exerted each moment by the draught to which the instrument is subjected.

MESSRS. COTTAM and HALLEN, engineers and agriculturists, of Winsley street, Oxford street, London, have recently patented an improved dynamometer, contrived with the intention of obviating the continual vibration of the indicator of the dynamometer formerly in use, which was caused (with reference to the plough) by the obstructions met with in the soil through which it was passing. These vibrations were so incessant, that the indicator could scarcely be discerned during the experiment. The improvement consists in the attachment of a small brass pump filled with oil, the piston of which has one or two small apertures. There being no outlet from the pump, it is evident that when any shock occurs, caused by a stone, root, &c., the oil having to pass from one side of the piston to the other, the suddenness is greatly diminished by the resistance, producing a corresponding effect upon the pointer, which, as these shocks are rapid, vibrates nearer the actual draught of the machine; which is the object in view, and not the measurement of any impediment, but a mean result of the whole. Mr. Pusey, in his "Experimental Inquiry on Draught in Ploughing" (Journ. Ray. Eng. Agr. Soc. vol. i. p. 219), speaks very favourably of this draught-gauge, and remarks (Ibid. p. 222): "Such is the goodness of Mr. Cottam's new draught-gauge, that we scarcely ever, I believe, differed by more than a quarter of a hundred weight, and often agreed to an eighth, or one stone."

DYSENTERY (Fr. dysenterie). See SHEEP, Diseases of.

EAR (Sax. eapa; Lat. auris). The organ of hearing in animals. In a horse, the ears should be small, narrow, straight, and the substance of them thin and delicate. They should be placed on the very top of the head; and their points, when stilled or pricked up, should be nearer together than their roots. When a horse carries his ears pointed forwards, he is said to have a bold or brisk ear. In travelling, it is considered an advantage when the horse keeps them firm. The exterior ears of the horse are merely organs for collecting sound;
consequently, he has a complete power over the muscles attached to them, and can turn them in every direction. It is probable that the organ of hearing is the safeguard of the horse in his natural state. He is ill adapted for combat; his swiftness of foot and his acuteness of hearing are therefore requisite to him of the utmost importance.

EAR MARK. A mark on the car by which shepherds know their sheep. Cattle, hogs, and other animals are sometimes marked in the same way, by notching, clipping, or slitting the ear.

EARNEST (Sax. eornor; Fr. arbre; Dan. ernts peuge). In commercial law, the sum advanced by the buyer of goods in order to bind the seller to the terms of the agreement. As to what amounts to sufficient earnest, Blackstone lays it down, that "if any part of the price is paid down, if it is but a penny, or any portion of the goods is delivered by way of earnest, it is binding." To constitute earnest, the thing must be given as a token of ratification of the contract, and it should be expressly stated so by the giver. (Clitty's Com. Law, vol. ii. p. 289; Mc Culloch's Com. Dict.)

EARS of Corn (Sax. stheber). The spike or head containing the seeds of wheat, &c.

In the United States the term ear as applied to grain, refers almost exclusively to that of Indian corn.

EARTH (Sax. ear). This word was anciently employed to signify one of the four elements of which all matter was supposed to be formed; namely air, fire, water, and earth. In the present period, the word in common language has two meanings; it implies either the globe we inhabit, or the soil on which plants vegetate. In this work it has reference to the latter. The soil, as well as the rocks, &c., of which our planet is formed, is composed of a variety of substances, such as lime, silica, alumina, magnesia, &c., to which chemists long since gave the name of earths; and although by the researches of Sir H. Davy and others, these earths have been shown to be, in reality, metallic oxides—that is, metals united with oxygen—yet the term earth is so well and so extensively known, that I should, even if this was intended to be a chemical dictionary, retain it. The following is the composition of the four earths most commonly met with by the farmer in his land, or in the crops which it supports:

Lime: a compound of a peculiar metal called

Silica, which is by modern chemists classed with the acids, is a compound of a metal called Silicon, &c.

In this place, however, our business is with the earths only so far as their uses to vegetation are concerned.

EARTHS, their Use to Vegetation. In the investigation of the use of the earths to vegetation, not only as regards their position as necessary portions of all cultivated soils, but as forming the essential constituents of most vegetable substances, several very important circumstances will present themselves to the notice of the cultivator. The order and the regularity with which these earths are found in plants is most remarkable; the harmony, too, with which the various chemical ingredients are arranged, the uniform manner in which they are absorbed by the roots of the plant and distributed in its tissues, cannot escape our attention, nor fail to excite our gratitude for the benevolence and the wisdom displayed in the contrivance. Thus we shall find, as we proceed in our researches (to give only a single instance), that the earth silica (lim) abounds in the straw of the wheat plant, where its presence helps to impart the requisite degree of strength and hardness to the stem; but scarcely a chemical trace of this earth is discoverable in the flour of the seeds of the same plant, for there its presence in our food would be worse than useless.

Let not, however, the reader, when he is considering the discoveries of vegetable chemistry, feel surprised that more has not been accomplished by the chemical philosopher in that important branch of science. There are many reasons why the discoveries in this branch of chemistry have been gradual, and only by slow degrees: he may be assured that the difficulties which attend the chemist when he is investigating the properties of organic substances, are more than usually numerous; for the living plant, in many instances, seems endowed with powers that appear even to neutralize the effects of chemical attraction and repulsion: thus the earths and alkalies, to give one instance only, are often found in juxtaposition with uncombined vegetable acids. The roots of most plants, also, are endowed with a remarkable capacity of absorption; not only do they absorb water, the gases of the atmosphere and those formed by putrefaction, but they take up earths, alkalies, and saline substances; and, besides doing this with a regularity which is almost unvaried, they exercise a power of absorbing certain saline bodies when dissolved with others in water, and of leaving the others in solution, which shows them to be endowed with properties of a very remarkable nature. Some curious experiments were long since made by M. Sausssure on this interesting question. "When various salts were dissolved at once in the same solutions," says Dr. Thomson, "and plants made to vegetate in them, it was found that different proportions of the salts were absorbed. The following
On examining the plants the salts absorbed were found in them unaltered. (Chemistry, vol. iv. p. 422.) In these experiments the cultivator will observe that the plants (which were Spotted Persicaria (Polygonum Persicaria) and the Bur-margold (Bidens tripartita), with their roots attached) absorbed the common salt with avidity, but that they rejected entirely the acetate of lime. The earths are, in all probability, always imbibed by the plant in a state of solubility; we know, in fact, that both lime and silica are, to a certain extent, soluble in water, and alumina is also very probably absorbed as a component of some of the soluble salts which contain this earth.

The part which the earth fulfils in the support of plants early attracted the attention of philosophers. The earthy ashes produced by the combustion of vegetable substances must have very soon indicated to mankind the real truth of the case, that there were certain solid substances found in vegetables which they could only derive from the earth they tenanted. That the soil furnished its earthly matter to the plant was, therefore, the natural conclusion of some of the Greek philosophers; and although their observations in this way were commonly very loose, and always general, yet when they decided, which they did with all gravity, that earth, air, fire, and water composed every thing on the earth, the vegetable world was of course included in the list; they still, however, thought that the chief use of the earth to plants consisted in keeping them upright, and furnishing them with a sufficient supply of moisture.

When the ancient naturalists came to the conclusion that the whole earth was composed of four elements, they founded their decision upon certain rude observations; but they did not stop there, they proceeded to confuse themselves by various incomprehensible or delusive phrases, such as more modern observers have too often imitated. Fire they regarded as the active principle of the universe, the source of both animal and vegetable life, the cause of renovation and decay. Earth they considered as the principle of fixity, of hardness, and of solidity. These rude, though sagacious observations, the early chemists, and then the alchemists, strongly confirmed by the mode in which they analyzed vegetable substances. They had only one mode of effecting this, that of subjecting them in a retort to dry or destructive distillation. By this mode the results are almost always the same; first the water of the plant comes over; then a volume of carburetted hydrogen and carbonic acid gases is driven off; and finally a quantity of earthy matters, united with various salts and potash remains at the bottom of the retort. We need hardly feel surprised, therefore, that after such an analysis, the chemists of old readied agreed with the naturalists that earth, air, and water, alone formed the vegetable world.

Evelyn, in 1674, wrote a work upon earth, in which he lauded its powers with much enthusiasm. "What shall I say," he exclaims, "Quid Divinum! the original of all fecundity; nor can I say less, since there was nor sacrifice nor discourse without it." And in another place he says (for Evelyn was exceedingly credulous), "Whatever then it be, which the earth contributes to the elements, whether it be a universal seminal virtue, so specified by the air, influences, and the genius of the climate, as to make that a cinnamon tree in Ceylon which is but a bay in England, is past my skill to determine; but it is to be observed with no little wonder, what M. Bernier in his history of the empire of the Mogul affirms to, as of a mountain there, which being on one side of it intolerably hot produces Indian plants, and on the other as intemperately cold, European and vulgar plants." That there is such valuable matter, however, in The Terra of Evelyn, whose modesty enhanced his great merits. Thus, in conclusion, he told his Fellows of the Royal Society, to whom his valuable essay was addressed, that it was merely "a dull discourse of earth, mould, and soil."

Fitzherbert, the earliest English writer upon agriculture (1582), did not pay any attention to earths, beyond the usual necessary routine of the farm; he confined himself entirely to practical details; not a trace of any thing like scientific inquiry is to be found in his Boke of Husbandry. John Worlidge, who published his System of Agriculture in 1669, thought it necessary, as he professed to "unveil the mystery of agriculture," to give the cultivator an explanatory chapter on the food of plants, in what he called "a plain and familiar method," and this he did in the true jargon of the alchemists; for the age of "the transmuters" was not yet over when Worlidge wrote. He gave, therefore, the husbandmen of those days a dissertation upon the universal spirit, or spirit of mercury, the universal sulphur, and the universal salt; but still, after all, he thought that the earth was the true food of plants, and that all the operations of the husbandman only tended to enable the roots of the plant to take up more earthy matter, and he devotes a chapter of his book to the"Soys and Manures taken from the Earth." But his ideas, like those of the alchemists, were usually a mixture of common sense and absurdity, too closely united to be always readily distinguishable by the good sense of the cultivator.

Jethro Tull, who wrote between 1730 and 1740, considered earth to be the sole food of plants. "Too much nitre," he tells us (p. 13, of his valuable Book on Husbandry), "corrodes a plant, too much water drowns it, too much air dries the roots of it, too much heat burns it; but too much earth a plant can never have, unless it be therein wholly buried: too much earth or too fine can never possibly be given to corn; for they never receive so much of it as to surfeit the plant." And again, he tells us in another place, "That which nourishes and augments a plant is the true food
of it. Every plant is earth, and the growth and true increase of a plant is the addition of more earth.” And in his chapter on the “Pasture of Plants,” Tull told his readers with great gravity, that “this pasture is the inner or internal superficies of the earth; or, which is the same thing, it is the superficies of the pores, cavities, or interstices of the divided parts of the earth, which are of two sorts, natural and artificial. The mouths or lacea of roots take their pabulum, being fine particles of earth, from the superficies of the pores or cavities, wherein their roots are included.”

Tull wrote with the enthusiasm of genius, and carried his admiration of the powers of the earth to support vegetation much too far; he was deceived, in fact, by the effects of his finely pulverizing system of tillage, and did not sufficiently attend to the fact, that there are many other substances in the commonly cultivated soils of the farmer besides the earths, and that so far from their being always the chief constituents of the soil, they very often form the smallest portion of even a highly productive field.

That the four earths of which all cultivated soils are composed are all the necessary food or constituents of vegetables, has, long since Tull wrote, been decided by the accurate investigations of the chemist. Of these, lime, either as a carbonate, or an acetate, or a sulphate, is by far the most generally present in plants; indeed, in one form or another, it is rarely absent from them. The presence of silica (flint) is almost equally general. Magnesia is less usually present, or, at least, it exists in smaller proportions; and the same remark applies to alumina (clay).

The quantity of the earths which is present in various vegetables is, therefore, a primary question for the cultivator’s guidance. This will be seen from the following tables:

<table>

The proportions of the earths contained in the commonly cultivated crops of the farmer have been ascertained by M. Schröder: this able chemist obtained from thirty-two ounces of the seeds of wheat (Triticum) of rye (Secale), barley (Hordeum vulgare), oats (Avena), and of rye-straw the following results:

<table>

(Gehlen, Journ. vol. ii. p. 525.)

The earth silica or flint abounds in almost every description of vegetable matter, especially in the grasses and Equisetum (horse-tail). In the Dutch rush it is so plentiful that that plant is used by the turner to polish wood, bone, and even brass. It forms so considerable a portion of the ashes of wheat-straw, that when these are exposed to the action of the bow-slice, it usually found also in the straw, and forms an opaque glass. Davy found it most copiously in the epidermis or outer bark of the plants he examined.

In the joints of the bamboo a concrete substance is found, which Pourcroy and Vaqueteau examined, and ascertained that it consists of 70 parts of silica, and 30 parts of colassa. This substance, which is named tabasheer, can only be furnished by the soil. (Gehlen, vol. ii. p. 112.)

This earth, according to M. Sauussure, constitutes 3 per cent. of the ashes of the leaves of oak gathered in May, 14.5 per cent. of those gathered in September, and 2 per cent. of the wood. In the ashes obtained by burning the wood of the poplar, it exists in the proportion of 3.3 per cent; of the hazel, 0.25 per cent; of the mulberry, 0.12 per cent; of the hornbeam, 0.12 per cent; 0.9 per cent. in peas (Pisum sativum); 61.5 in the straw of wheat; 0.25 in the seeds; 57.0 per cent. in the chaff of barley; 35.1 in its seeds; and in the oat plant 60 per cent.

Lime is, if possible, still more generally present in all plants than silica. “The saldsoda,” says Dr. Thomson, “is the only plant in which we know for certain it does not exist.” (Syst. of Chem. vol. iv. p. 190.) It is, however, united with carbonic acid as carbonate of lime; or it exists as the base of some other salt, such as in oxalate of lime, or in sulphate of lime (gypsum). It was found in the ashes remaining after the combustion of oak wood, at the rate of 32 per cent., by M. Sauussure. In that of the poplar at the rate of 27 per cent. He discovered also 8 per cent. in those from the wood of the hazel; 56 in those of the mulberry wood; 26 in the hornbeam; 14 in the ripe plant of peas; 1 per cent. in the straw of the wheat, but not any in its seeds; 12 in the chaff of barley, but none in either its flour or its bran; neither did he find any in the oat plant; but then, in the ashes of the leaves of the fir (Pineus abies), raised on a limestone hill, he found 43.5 per cent.

Alumina, as I have elsewhere observed, is found in most vegetables, but in much smaller proportion than either silica or carbonate of lime, and the same remark applies to magnesia. M. Schröder found, as we have before seen, in 2 lbs. weight of the seeds of wheat only 10ths of a grain of alumina, in rye 1g, grains, in barley 4g, grains, in oats 4g, grains, and in rye-straw 9g, grains. In 12 ounces of wormwood there are about 5 grains of alu-
minas. This earth, however, necessarily exists in all fertile soils as the food of plants; for although the proportions in which it is found are rather small, yet still there is no reason to believe that its presence is not essential to the healthy growth of the plant. M. Saussure found the ashes of the 

\[ \text{Pinnus abies} \]

growing on a granite and on a calcareous soil, to contain nearly the same quantity of alumina (15 per cent. on the calcareous and 16 per cent. on the granite), although these soils differed widely in the proportion of the alumina they contained; for 100 parts of each wood were composed of:

(Thomson's Chem. vol. iv. p. 317.)

Such are the earths which constitute all cultivated soils, and such is the necessary proportion in which they form the constituent elements of some of the plants which they support. In the soils of the cultivator, however, they exist in an endless variety of proportions: thus, I found 68-5 per cent. of silica in the gravelly soils of Great Totham, in Essex, and 62 in those of Kintbury, in Berkshire. Davy discovered about 50 per cent. in the soil of the Endsleigh Pastures in Devonshire, 54 in that near Sheffield Place in Sussex, 15 in the turnip soils of Holkham in Norfolk, 32 in the finely divided matters of the wheat soils of West Drayton, and about 97 per cent. in the soil of Bagshot Heath. Mr. George Sinclair found about 66 per cent. in the grass garden of Woburn Abbey.

Of alumina, or pure earth of clay, the proportions are equally varying. I ascertained the presence of 4-5 per cent. of this earth in a gravelly soil of Thurstable in Essex, and 6-5 in one at Kintbury in Berkshire. Mr. G. Sinclair found 14 per cent. in the soil of the grass garden at Woburn Abbey. Davy detected 8-5 per cent. in that at Endsleigh, 6-5 in one at Croft Church in Lincolnshire, 7 in that in Sheffield Place, 11 in that of Holkham, 29 in a field at West Drayton, and about 1 per cent. in the soil of Bagshot Heath.

Of carbonate of lime, the presence is just as varying in amount as that of the other earths. I found 18 per cent. in a soil at Totham, and 19 per cent. in a soil at Kintbury; Sinclair, 2 per cent. in the soil of the Woburn Abbey grass garden. Davy discovered 8 per cent. in that from Croft Church, 3 per cent. in that of Sheffield Place, 63 per cent. in the finely divided matters of the soil from Holkham, and about 1 per cent. only in the soil from Bagshot.

The farmer, however, must not conclude, that by merely mixing the pure earths, silica, lime, and alumina together in the most fertile proportion, a soil can be formed on which plants will flourish, for such is a very erroneous conclusion. The attempts which have been made to make plants flourish in the pure earths have failed utterly when they have been watered with pure water; yet a totally different result I have invariably experienced when I have employed an impure solution or liquid manure. My trials have been entirely supported by those of M. Giobert, who having formed of the four earths, silica, alumina, lime, and magnesia, a soil in the most fertile proportion, in vain essayed to make the plants flourish in it when watered with pure water only; but every difficulty was removed when he moistened it with the water from a dunghill, for they then grew most luxuriantly; and M. Lampadius still further demonstrated the necessity for, and the powers of such an additional to the soil; for he formed plots composed only of a single earth—namely, pure lime, pure alumina, or pure silica—and planted in each different vegetables, watering them with the liquid drainings from a dunghill, and he found that plants on all of them flourished equally well. The equal proportion of a soil ever constitute, in fact, its most fertilizing portion; and if by any artificial means the richest mould is deprived of these, as by repeated washings in cold or boiling water, the residuum or remaining solid matter is rendered nearly sterile. This fact, first accurately demonstrated by M. Saussure, I have since confirmed by a variety of experiments. Neither must the cultivator imagine that these carefully considered conclusions, the results of often-repeated laborious experiments, are erroneous, because transparent water, apparently pure, when viewed in water-glasses, or in irrigation, promotes the growth of bulbs, grass, &c., since the very purest spring water, even rain water, contains foreign substances; and when only chemically pure water is employed to water plants, they cannot be made to flourish. I have fruitlessly varied the attempt in several ways. All the experiments of Dr. Thomson were equally unsuccessful, the plants vegetating only for a certain time, and never perfecting their seeds. Similar experiments were made by Hassenfratz, Sinclair; and others, with the same unfavourable result. Duhamel found that an oak, which he had raised from an acorn in common water, made less and less progress every year. The florist is well aware that bulbous roots, such as those of hyacinths, tulips, &c., which are made to grow in water, unless they are planted in the earth every other year, at first refuse to flower, and finally cease even to vegetate. Moreover, it has been unanswerably shown by many very accurate experiments, at the repetition of which I have personally assisted, that the quantity of nourishment or solid matters absorbed by the roots of plants is always in proportion to the impurity of the water with which they are nourished; thus some common garden beans were made to vegetate under three different circumstances; the first were grown in distilled water, the second were placed in sand and watered with rain water, the third were sown in garden mould. The plants thus produced, when accurately analyzed,
were found to yield the following proportion of ashes—

<table>

The mode in which the earths are absorbed by the roots of the plant is, it is almost certain, by means of their solution in water, for both carbonate of lime and silica are, in small proportions, soluble in water; they exist together in many springs; and they were both found in the water of the Clyde by Dr. Thomson, in that of the Thames by Dr. Bostock, and in the springs of Upsala, celebrated for their purity, by Bergman. Alumina, as far as we know, is not soluble in water, but then it exists in very small proportions in plants; and the soluble salts of which it is the base may serve to yield this earth to vegetables: the earth itself is soluble in ammonia.

The way in which soils are gradually formed by the action of the atmosphere upon the hard primitive rocks has been well explained by Davy, and is a natural process which cannot but be interesting to the farmer. I merely slightly alter his words in the following account of this important natural phenomenon. It is not difficult to comprehend the manner in which this change is effected, and rocks converted into soils, by referring to the instance of soft granite or porcelain granite. This substance is composed of three ingredients, quartz, feldspar, and mica. The quartz is almost pure silicious earth in a crystalline form. The feldspar and mica are very compound substances: both contain silica, alumina, and oxide of iron; in the feldspar there is usually lime and potash; in the mica, lime and magnesia.

When a granitic rock of this kind has been long exposed to the action of the atmosphere, the lime and the potash contained in its constituent parts are acted upon by water or carbonate acid; and the iron, which is almost always in its least oxidized state, tends to combine with more oxygen; the consequence is, that the feldspar decomposes, and likewise the mica, but the first the most rapidly. The feldspar, which is, as it were, the cement of the stone, forms a fine clay; the mica, partially decomposed, mixes with it as sand, and the undecomposed quartz appears as gravel, or sand of different degrees of fineness. As soon as the smallest layer of earth is thus formed on the surface of a rock, the seeds of lichens, mosses, and other imperfect vegetables, which are constantly floating in the atmosphere, and which have made it their resting-place, begin to vegetate; their death, decomposition, and decay afford a certain quantity of organic matter, which mixes with the earthy matter of the rock. In this improved soil, more perfect plants are capable of subsisting; these in their turn absorb nourishment from water and from the atmosphere, and as these, too, decay, afford more new materials to those already provided; and the decomposition of the rock still continues. At length, by such slow and almost imperceptible processes, a soil is formed in which even forest trees can fix their roots, and which is fitted to reward the labours of the cultivator.

Where successive generations of vegetables have grown upon a soil, unless they have been carried off by man or consumed by animals, the vegetable matter increases to such an extent that the soil approaches to peat in its nature. Poor and hungry soils are commonly produced by the decomposition of the granite and sandstone rocks: such soils usually remain for ages with only a thin covering of vegetation. The soils produced by the same gradual means on the limestones, chalks, and basalts, are often clothed by nature with the perennial grasses, and afford, when ploughed up, a rich bed of vegetation for every species of cultivated crop.

The quantity of moisture which a soil, or the earths of which it is chiefly composed, contain, influences to a very material extent its fertility. This not only differs in different seasons, but this power varies very considerably in soils, according to their chemical composition. This was experimentally decided by Professor Schubler, of the University of Tubingen, in his "Agronomy, or Principles of Agricultural Chemistry," for a translation of which the English farmer is indebted to Mr. Hudson, the present excellent Secretary to the Royal Agricultural Society of England,—a translation of which I have largely availed myself in this paper. (Journal of Roy. Ag. Soc. vol. i. p. 177.) M. Schubler found that a cubic foot of different soils, when thoroughly saturated with water and when completely dried, weighed as follows:

<table>

The result of these trials will be useful to the farmer in explaining to him the reason why, on account of their requiring more or less moisture, certain crops flourish best on particular soils; and even in the carriage of the earths he will perceive that their weight in the wet or dry state is much greater than some persons suppose.

The next important inquiry instituted by the same excellent chemist, was the relative degree of tenacity with which different soils retain the moisture when exposed under similar circumstances to the action of the atmosphere; and he found that they parted with their moisture according to the following rate:

<table>
<thead>
<tr>
<th>Kind of Earth</th>
<th>Excess thrown from 100 parts of absorbed water in four hours.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Silicious sand</td>
<td>58-4</td>

</tbody>
</table>

In these experiments the soils were spread out to dry very thinly over a plate of metal; but in the following comparative trials (to render the results in all respects more similar to those which the cultivator would experience), the soil was exposed to the atmosphere in masses of an inch in depth:

The amount of the relative contraction of different soils, when they are deprived of their moisture, is another equally important question to the farmer to be ascertained. "Many of them," says M. Schubler, "become contracted into a narrower space in drying, and in consequence of this circumstance cracks and fissures frequently occur in land, and have an injurious effect on the vegetation, as the finer roots, which often ramify horizontally, and not unfrequently supply to the plants the greater part of their means of nourishment, are, by such contractions, either laid bare of soil or torn asunder. In order to subject soils to comparative experiments on this point, the following plan may be adopted. We either form of the earths, in their wet state, large cubic pieces of equal size, being at least ten-twelfths of an inch in height, breadth, and length, or we let such earths be fitted and dried one after another in an accurately worked cubic inch; after some time, when the weight of these cubes of earth ceases to change by further drying, we measure the dimensions of the cube by means of a rule on which the tenths of lines can be distinguished, and may thus calculate easily the volume of the earth, and consequently ascertain the diminution in bulk which has been caused by the drying. The experiments which I made with the following earths exhibited on this point the subjoined differences:

<table>

</tbody>
</table>

Such is the effect upon various soils of depriving them of their moisture. In these chemical investigations the farmer will see how entirely they confirm his own observations. The heavy clay soils, he well knows, are the most contracted by exposure to the heats of summer; the sands the least affected of any.

A still more important property of soils, their attraction for the aqueous vapour of the atmosphere, is next to be considered—a property the importance of which to the cultivator, Sir H. Davy long since saw in its true light, and his observations cannot be too often quoted, since they well illustrate and enforce, amongst other things, the truth of the great Tullian system of agriculture: of the advantages of finely dividing the soil, of the subsoil plough, and of the horse-be husbandry. "The power of the soil to absorb water by cohesive attraction," said this great chemist, "depends in a great measure on the state of division of its parts; the more divided they are, the greater is their absorbent power. The different constituent parts of soils likewise appear to act, even by cohesive attraction, with different degrees of energy; thus vegetable substances seem to be more absorbent than animal substances, animal substances more so than compounds of alumina and silica, and compounds of alumina and silica more absorbent than carbonates of lime and magnesia; these differences may, however, possibly depend upon the differences in their state of division, and upon the surface exposed. The power of soils to absorb water from air is much connected with fertility; when this power is great, the plant is supplied with moisture in dry seasons; and the effect of evaporation in the day is counteracted by the absorption of aqueous vapour from the atmosphere by the exterior parts of the soil during the night. The stiff clays, approaching to pipe-clay in their nature, which take up the greatest quantity of water when it is poured upon them in a fluid form, are not the soils which absorb most moisture from the atmosphere in dry weather; they cake, and present only a small surface to the air, and the vegetation on them is generally burnt up almost as readily as on sands. The soils that are most efficient in supplying the plant with water by atmospheric absorption are those in which there is a mixture of sands and divided clay, and carbonate of lime, with some animal or vegetable matter; and which are so loose and light as to be freely permeable to the atmosphere. With respect to this quality, carbonate of lime and animal and vegetable matter are of great use.
EARTHS.

1000 parts of horse dung dried in a temperature of 160 degrees, absorbed, by exposure for three hours to air saturated with moisture and of the temperature of 62 degrees, 145 parts. 1000 parts of cow dung, under the same circumstances, absorbed 130 parts. 1000 parts pig dung 120 parts. 1000 parts sheep dung 61 parts. 1000 parts pigeon's dung 50 parts. 1000 parts of a rich alluvial soil, worth two guineas per acre (rent), 14 parts.

The following were dried at 212 degrees:

1000 parts fresh tanner's bark — 115 parts. 1000 parts putrefied tanner's bark — 145 parts. 1000 parts refuse marine salt sold as manure — 491 parts. 1000 parts sand — 39 parts. 1000 parts burnt clay — 29 parts. 1000 parts coal ashes — 14 parts. 1000 parts lime — 11 parts. 1000 parts sediment from saltpans — 10 parts. 1000 parts crushed rock salt — 9 parts. 1000 parts gypsum — 4 parts. 1000 parts chalk — 4 parts.

(Johnson on Fertilizers, p. 41.)

Davy's experiments and my own are confirmed by those of M. Schubler, who varied his observations at intervals of three days; his results were as follows:

<table>

</table>

This attractive power of the earths and of the plants for the aqueous vapour and the oxygen gas of the atmosphere are, as I have on more than one occasion contended, two of the most important facts to be kept in mind by the farmer, with regard to the deepening and pulverization of his soils. The power of absorbing moisture is a power which all plants possess in a certain measure, but some in such a perfect degree as to depend entirely upon it for all the moisture they need. The aloe, the agave, and many of the native plants of the East, nearly support themselves in the same way; the lichens and some of the mosses of this country also do the same. The quantity of water consumed by plants, when in a state of healthy vegetation, is in fact so great that, if it was not for the gentle steady supply thus imperceptibly furnished to the soil by the atmosphere, vegetation would speedily cease, or only be supported by incessant rains. Thus Dr. Hales ascertained that a cabbage transmits into the atmosphere, by insensible vapour, about half its weight of water daily; and that a sunflower, three feet in height, transpired in the same period nearly two pounds' weight. (Veg. Stat. vol. i. pp. 5—15.) Dr. Woodward found that a sprig of mint, weighing 27 grains, in seventy-seven days emitted 2543 grains of water. A sprig of spearmint, weighing 27 grains, emitted in the same time 2558 grains; a sprig of common nightshade, weighing 49 grains, evolved 3708 grains, and a Lathyrus of 98 grains emitted 2561 grains. (Phil. Trans. 1699, p. 193.) "The power of soils to absorb moisture," says Davy, "ought to be much greater in warm or dry countries than in cold or moist ones, and the quantity of clay or vegetable or animal matter greater. Soils, also, on
declivities ought to be more absorbent than in plains, or in the bottom of valleys. Their productiveness, likewise, is influenced by the nature of the subsoil, or the stratum essentially on which they rest. When the soils are immediately situated upon a bed of rock or stone, they are much sooner rendered dry by evaporation than when the subsoil is of clay or marl; and a prime cause of the great fertility of land in the moist climate of Ireland is the proximity of the rocky strata to the soil. A clayey subsoil will sometimes be of material advantage to a sandy soil; and, in this case, it will retain moisture in such a manner as to be capable of supplying that lost by the earth above, in some degree compensating the consummation of plants." (Davy's Lectures, p. 186.)

It has been shown by the experiments of M. Saussure, with some sprigs of peppermint, that when supported by pure water only, and allowed to vegetate for some time in the light, they nearly doubled the portion of carbon which they originally contained. (Recherches sur la Fe. 51.) This they could have procured only from the atmosphere; and, under these circumstances, there is now little doubt of the correctness of the conclusion of M. Berthollet, that plants, by means of their roots and leaves, have the power of decomposing the water as well as the carbonic acid of the atmosphere, and furnishing, with these elements, new combinations. How essential a free access of the atmosphere is to the roots of plants was long since shown by M. Saussure, who found that oxygen gas is absorbed by the roots of plants as well as by their leaves, and that it is at the roots united with carbon, and transmitted to the leaves to be decomposed. Even the branches absorb oxygen; in its absence flowers will not even expand. (Thomson's Chem. vol. iv. p. 353.) It has been proved that their vegetation is greatly increased by nourishing them with water impregnated with oxygen gas; hence, too, the superiority of rain-water. Some remarkable experiments were made by Mr. Hill, demonstrating of the great benefits plants derive from oxygen gas being applied to their roots: hycinths, melons, Indian corn, &c., were the subjects of the experiments. The first were greatly improved in beauty, the second in size, the last in vigour. This, too, is another use of increasing the moisture of the soil, by deep and complete ploughings, for M. Humboldt and M. Schubler have clearly shown that a dry soil is quite incapable of absorbing oxygen gas. Thus, it must be evident to the most listless observer, that the more deeply and finely a soil is pulverized, and its earths rendered permeable, the greater will be the absorption by them of both oxygen and watery vapour from the surrounding atmosphere.

It is perhaps needless to prove that the roots of commonly cultivated plants will penetrate, under favourable circumstances, much greater depths into the soil in search of moisture than they can, from the resistance of the case-hardened subsoil, commonly attain. Thus, the roots of the wheat plant, in loose deep soils have been found to descend to a depth of two or three feet, or even more: and it is evident that if plants are principally sustained in dry weather by the atmospheric aqueous vapour absorbed by the soil, that then that supply of water must be materially increased, by enabling the atmospheric vapour and gases, as well as the roots of plants, to attain to a greater depth; for the earth, &c., of the interior of a well pulverized soil, be it remembered, continues steadily to absorb this essential food of vegetables, even when the surface of the earth is drying in the sun.

By facilitating the admission of air to the soil another advantage is obtained, that of increasing its temperature. The earths are naturally bad conductors of heat; but it is a well-known fact, that at the siege of Gibraltar, the red hot balls employed by the garrison were readily carried from the furnaces to the batteries in wooden barrows, whose bottoms were merely covered with earth. Davy proved the superior rapidity with which a loose black soil was heated, compared with a chalky soil, by placing equal portions of each in the sunshine; the first was heated in an hour from 65° to 88°, while the chalk was only heated 69°. This trial, however, must not be regarded as absolutely conclusive, since the surface of the black soils naturally increases more rapidly in temperature when exposed to the direct rays of the sun than those of a lighter colour. A free access of the air to the soil also adds to their fertility, by promoting the decomposition of the excredy matters of plants and other organic substances of the soil.

In the truth of these conclusions and laborious experimental researches of the chemist, does not the practical testimony of the ablest cultivators of all ages and in all countries concur? Thus, in enforcing the advantages of rendering the soil more completely permeable by the atmosphere, nearly two thousand years since, Cato asked the Italian farmers, “What is good tillage?” To plough. “What is the second?” To plough. The third is to manure. Cato, however, mistook the cause of the benefit, for he says, “He who stirs his olive ground oftener and deepest will plough up the very slender roots; if he ploughs ill, the roots will become thicker, and the strength of the plants will go to the bottom.” (Cato, 35.) The farmer, and all in his employ, naturally conclude that the advantages of paring and burning, says, “The heat opens more ways and hidden vents for the air, through which the dews penetrate to the embryo plant.” (Georg. i. 90, 91.)

And at this very period do not the best of England’s agriculturists find the greatest advantage from stirring the ground between their rows of drilled turnips, which only operates so beneficially to the plants, by promoting the access of the air to their roots; and that, too, on soils where a weed is hardly to be seen? Is not one great object of fallowing to produce by pulverizing and deepening the soil the same result? Did not Jethro Tull labour long, and sometimes too sanguinely, in illustrating the same position? And does he not support almost all the observations of the chemist, as to the attraction of the earth for the gasses and aqueous vapour of the atmosphere, when he says—I have had the experience of a multi-
From these experiments, the farmer will perceive that the popular ideas, with regard to the quality of soils when they are denominated hot and cold, are nearly accurate. He will see that sandy soils absorb the heat of the sun faster than any others, but then their rate of cooling is equally great;—more rapid in their transitions from heat to cold than any others, the crops which they produce are commonly thin; and to these rapid transitions we may assign one reason for the poverty of the produce. The clays, on the contrary, which imbibe the sun’s rays more slowly, retain their heat much longer.

There are several other properties of the earths with which it is highly desirable that the cultivator should be acquainted: thus, the resistance which soils offer to the plough or the spade, in their wet and dry state, is a question on several accounts highly interesting to the farmer. This property of the soil has also been examined by Professor Schubler, and the result of his experiments will be found in the following table:—

| Kind of Earth | Firmness, that of clay being 100. | Adhesion to agricultural implements on a surface of one square foot with

From these laborious researches of the chemical philosopher the intelligent farmer may derive many new and important conclusions with regard to the improved cultivation of the earth. They may serve to explain to him one great reason why following and pulverizing the soil, either by machinery or by the mixture of chalk or sand with the heavier clay soils, promotes so decidedly, or so permanently, their fertility. And, again, the advocate for all old customs and obsolete modes of tillage may hence, among other things, learn why it is that deep ploughing, either by the common or by
EARTH-BORD.

It might become a matter of curious inquiry, how far this desire of earth in cattle has affinity to that of the human stomach, which leads the Otonacs, a South American tribe, to eat clay. It is an unctionous clay, containing an oxide of iron; and during some months, when provisions are scarce, the females eat about three-quarters of a pound of clay daily, and he does not suffer nor become lean upon it. The negroes on the coast of Guinea, and the natives of Java, and of some of the other islands of the Indian Archipelago, are also earth-eaters; and in this and many European countries, pregnant women, and young girls in a state of disease connected with the uterine function, also evince a strong inclination to eat earth.

Among quadrupeds, earth-eating is not confined to the horse and ox tribes; for, when pressed for food, wolves in the north-east of Europe, reindeer and kids in Siberia, all eat clay. It is probable that the earth operates as a mechanical stimulus to the stomach, and abates the sensation of hunger, which always attends certain diseased conditions of the stomach. But, whatever may be the cause, this instinctive longing for earth in horses, cows, and oxen should not be overlooked, and the animals should be supplied with it when they are stall-fed.

EARTH-NUT (Bumina flexuosa). The common earth-nut, kipper, or pig-nut, for it is known by all these names, is a perennial plant growing in sandy or gravelly meadows, pastures, orchards, and woods; flowering in May or June. The root is eatable, nearly globular, black, internaiy white, aromatic, sweet, and mucilaginous, with some acrimony. The stem is a foot high or more, striated, with long, narrow, acute leaves; the radicle leaves are twice or thrice pinnatifid. The flowers are in umbels; they are pure white. The roots are at present searched for only by hogs, who devour them with avidity; but as they are little inferior to chestnuts, they might form an agreeable addition to winter desserts, eaten either raw, boiled, or roasted. (Willic's Don. Encycl.)

EARTH-WORMS (Lumbricus, Linn.). Well-known molluscous animals, which are common in all parts of the county, at little depths beneath the surface of the earth. White, in his Nat. Hist. of Selborne, speaking of their effects on the soil in promoting vegetation, says, "The most insignificant insects and reptiles are of much more consequence, and have much more influence in the economy of nature, than the inconsiderable are aware of; and are mighty in their effect from their minuteness, which renders them less an object of attention, and from their numbers and fecundity; earth-worms, though in appearance a small and despicable link in the chain of nature, yet, if lost, would make a lamentable chasm. For, to say nothing of half the birds and some quadrupeds which are entirely supported by them, we have reason to be equal promoters of vegetation, which would proceed but lamely without them, by boring, perforating, and loosing the soil, and rendering it pervious to the rain and the fibres of plants, by drawing straws and stalks of leaves and twigs into it; and most of all, by throwing up such infinite numbers of

436

the subsoil plough, produces such beneficial results; how the gases and aqueous vapour of the air are hence rendered more serviceable to the roots of his crops; and how it is that this free passage of these elastic fluids, first caused by the action of the plough, is preserved and facilitated by that of the common or the horse-hoe. Such researches, too, into the important properties with which the Creator has endowed the soil will be serviceable to the cultivator in even an indirect manner. These investigations will, assuredly, suggest to him the very reasonable conclusion, that there may be yet other chemical properties hidden in the land, which will serve to awaken the curiosity, and reward the labours of future scientific cultivators for many succeeding generations. (Brit. Farm. Mag. v. p. 1.) See Mixture of Soils, Analysis of Soils, Absorption, Chalk, Humes, &c.

EARTH-BOARD. That part of a plough which turns over the earth. It is generally termed the mould-board. See Plough.

EARTH-BUILDINGS. Buildings formed by rammed or compressed earth or clay. This kind of building is supposed to have been known at a very early period, and is still much in use in the southern parts of France. Not only the walls of the houses, but garden walls are formed in the same manner, and of the same materials in many parts of Normandy. In some instances, boards are placed between the layers of clay, and form a kind of framework, which increases the strength of the wall.

Clay cottages are not uncommon in some parts of England; but they are not constructed in the above-mentioned manner.

EARTH, EATING OF. Stall-fed cattle, and horses which have not the opportunity of plucking up the roots of grass, evince a great partiality for earth. It is seldom that a cow will pass a newly-raised mole-hill without muzzling into it, and devouring a considerable portion of it. This is particularly the case when there is any degree of indigestion, and it probably acts as a sort of gentle purgative. It is stated by Mr. Youatt (On Cattle) that the celebrated Kinton ox always had a basket of earth standing near him, of which he ate a considerable quantity. When decomposition commenced, and the ascendent principle began to be developed, and the animal felt uneasiness on that account, he had recourse to the mould; and the acid uniting itself to the earth, the uneasy feeling was relieved. It is also probable that a purgative neutral salt was manufactured in the paunch, but this would depend on the nature of the earth. The absorbent or alkaline earth taken up with the roots of grass by sheep, also neutralizes the acids of the stomach. (Lib. of Use. Know. "Sheep," p. 3; "Cattle," p. 104 —317.) It is usual to allow sucking calves to have access to chalk. In the stomachs of almost all young animals, man not excepted, there is a tendency to form superabundant of the which, if not corrected, impairs digestion, and interferes with the assimilative function, that which converts the chyle into the animal tissue or substance of the body. The importance, therefore, of correcting this, by the administration of absorbed earths, is obvious.
EEADEN MANURES.

EADDER.

lumps of earth, called worm-casts, which being their excrement, is a fine manure for grain and grass. Worms probably provide new soil for hills and slopes, where the rain washes the earth away, and they affect slopes probably to avoid being flooded. Gardeners and farmers express their detestation of worms: the former, because they render their walks unsightly, and make them much work; and the latter, because, as they think, worms eat their green corn. But they would find that the earth without worms would soon become cold, hard, botched, and void of fermentation, and consequently sterile; and besides, in favour of worms it should be hinted that green corn, plants, and flowers are not so much injured by them as by many species of Culeoptera (scarabaeas) and Tylabe (long-legs) in their larve or grubs state, and by unnoticed myriads of small shell-less snails, called slugs, which silently and imperceptibly make amazing havoc in the field and garden. Worms work most in the spring; and are out every mild night in the winter: they are very prolix. Quot. Journ. Agric. vol. ii. p. 145.)

Worms are readily destroyed by the application of common salt, sown broadcast at the rate of five or six bushels per acre; or on grass-plats, by the application of lime-water, or rather milk of lime, which is readily made by stirring for ten minutes a pound of hot lime in four or five pailsfull of water. But, for the reasons already given, they should not be destroyed. Earth-worms are viviparous, their eggs are hatched in the body, and the young are expelled alive. They generally come out of the earth during the month of June to copulate.

EARTH MANURES. These are the most universal of all fertilizers. In England they are chiefly limited to three, viz. chalk and lime, clay or alumina, sand or silex. In the United States, where no chalk is found, its place is well supplied by lime and calcareous marls, which last, in New Jersey, Delaware, Maryland, and Virginia, are used to the greatest advantage by farmers. Then again the green sand or silicate of potash, found in the states mentioned, proves to be a powerful mineral fertilizer. With these may be classed the coal, or other ashes produced by the combustion of peat, turf, and other vegetable substances, the composition of which is usually similar to that of the soils on which the combustible matter is produced. Ashes from chalk soils usually abound in carbonate of lime and gypseum, which is produced in the chalk by the gradual decomposition of the iron pyrites which most chalk contains; while those from clay lands are generally of alumina and sand. Those which are brought from the seashore almost always contain a considerable quantity of soda, and some common salt. There are no researches more likely to amply repay the cultivator than the investigation of the composition of his soils. All the difference between a fertile soil and the poorest cultivated land consists in the presence of the indispensable constituents of a soil in proportions that are more or less profitable. The addition of the desired substance, whether organic or inorganic, constitutes the fertilizing ingredient. Davy long since remarked that “Fertility seems to depend upon the state of division and mixture of the earthy materials and the vegetable matter. In ascertaining the composition of fertile soils, with a view to their improvement, any particular ingredient which is the cause of their unproductiveness should be particularly attended to; if possible, they should be compared with fertile soils in the same neighbourhood, and in similar situations, as the difference of composition may, in many cases, indicate the most proper methods of improvement.” (Agrcultural Chemistry, p. 203.)

Thus, either peat, or chalk, or clay is an excellent permanent addition to sandy soils. Chalk and sand improve the texture and productive ness of clays. To peat, the earths are all more or less permanent fertilizers; lime removes the excess of sulphate of iron (green vitriol); chalk is equally efficacious in what the farmer calls acid or sour soils. This class of manures differs from the organic and saline, in this highly important yet seldom sufficiently remem bered quality, that as they are more frequently employed in larger quantities, than either of the other two, so their beneficial influence on the soil far exceeds in duration all others.

EARWIG (Forficula auricularia, Linn.). A well-known insect, which is common in damp places, and often found in numbers under stones, and beneath the bark of trees. They do much damage in gardens, by preying upon the fruit. The English common name, and also the French pierre-coeuré, relate to a habit absurdly attributed to these insects, of penetrating the ears. (Brandes’s Diet. of Art.)

It is a curious fact that the earwig sits upon her eggs like a hen; and when the young are hatched, they creep under the mother, like a brood of chickens under a hen. De Geer, who has observed the habits of this insect, says, the parent will sit over them for hours. She usually carries them about on her back, until they are able to provide for themselves. One of the species of forficula, namely, F. minor, has wings, and flies in groups.

They are very injurious to flowers, eating holes in the blossoms, and otherwise disfiguring them, particularly the dahlia; and Mouffet says that “ox hoofs, hog’s hoofs, or old cats things are used as traps for them by the English women, who hate them exceedingly, because of clove-gillflowers that they eat and spoyl.” It is common with English gardeners to hang up, among the flowers and fruit-trees subject to their attacks, pieces of hollow reeds, lobster claws, and the like, which offer enticing places of retreat for these insects on the approach of daylight, and by means thereof great numbers of them are obtained in the morning. The little creeping animal, with numerous legs, commonly, but erroneously, called earwig in America, is not an insect; but of the true earwig we have several species, though they are by no means common, and certainly never appear in such numbers as to prove seriously injurious to vegetation. (Harris’s Treat. of Insects.)

EDDER. A small, straight shoot of ash, hazle, oak, or any other kind of flexible wood used for binding the tops of hedges.

437
EGLANTINE.

EGLANTINE, or EVET (Salamantra). A small kind of lizard, that chiedy lives in the water. As the newt is an amphibious animal, it requires to ascend frequently to the surface of the water, to take fresh air into its lungs. 

EGGS (Fr. œufs; Germ. ei; Lat. ovum). The ova of birds and oviparous animals. The shell of the egg is lined throughout with a thin but tough membrane, called pellicula ovi; which, dividing at or near the obtuse end, forms a small bag—the air follicle. This membrane weighs about 2·35 grains in an egg of 1000 grains in weight. It contains what is called the albumen or white, and the vitellus or yellow. The white consists of two distinct parts, one of which is a delicate membrane forming a series of cells, which enclose the other, or fluid part. It has the well-known property of being congelated by heat. It consists of 12 parts of albumen, 27 of mucus, 0·3 of salts, and 85 of water, in a hundred parts. The yolk consists of oil, suspended in water by means of albumen, and held in a membranous sac, the yolk-bag; each end of which is twisted, to form what is called the chalaza, intended to preserve the yolk in such a position that the cicatricula, or rudimental embryo, shall always be uppermost. The yolk consists of 28·75 of yellow oil and crystalizable fat, with traces of sulphur; 17·47 of albumen, containing phosphorus, and 53·8 of water. The relative weights of these parts, in an egg weighing 1000 grains, are, 106·9 shell and membrane, 604·2 albumen, and 288·9 yolk. The egg loses 2 or 3 per cent. of its weight when boiled in water. The white is more easily digested than the yolk; and both are more digestible in the soft than in the hard state. The changes which the hen's egg undergoes during incubation have been described by Sir E. Home (Phil. Trans. 1822, p. 339), and illustrated by a beautiful series of plates, after drawings by Bauer. The same volume also contains a valuable paper, by Dr. Prout, on this subject, but chiefly treating of the chemical changes of the egg during that process. The egg does not receive its outer coat, or pellicule, until it arrives at that part of the ovum, which is called the uterus; and not its shell until it has passed through one half of the uterus. Eggs are sometimes expelled without shells, and are called oon-eggs. The specific gravity of new-laid eggs at first rather exceeds that of water, varying from 1·08 to 1·09; but they soon become lighter, and swim on water, in consequence of evaporation through the pores of the shell. The mean weight of a hen's egg is about 87·5 grains.

Hen's eggs are decidedly wholesome; and when new laid, are an agreeable and nourishing food. Vast quantities of eggs are brought from the country to London, and other great towns. It is stated in the Quart. Journ. of Agr. vol. iii. p. 1077, that, about 15 years ago, the number of eggs exported from Berkwick-upon-Tweed to London amounted to 30,000; worth a year.

The trade in eggs is of great value and importance. It appears from official statements, that the eggs imported into England from France amounted to 60,000,000 a year; and presuming them to cost, on an average, 4d. per dozen, it follows that the English pay the French above 83,000l. a year for eggs; and supposing that the freight, importer's and retailer's profit, duty (10d. per 120), &c. raise their price to the consumer to 10d. per dozen, their total cost will be 213,000l. The number of eggs imported into England from various parts of the Continent, for the year ending January 5, 1839, was 83,745,723; and the gross amount of duty received for the same was 29,111l. The Netherlands and the Channel islands furnish a large quantity of the eggs consumed in England. (McCutlock's Com. Dict.)

See FOWLS.

A new method of preserving eggs, by packing them in salt with the small end downwards, and by which they have been kept perfectly good for eight or nine months, will, it is believed, enable the inhabitants of portions of our country where these abound to make them profitable. Thousands of bushels may be sent off to the Atlantic markets. Great quantities are used in France; and as the duty on them in England is so small (not 2 cents per dozen,) they might bear exportation. They have been gathered and sold at the West as low as 90 cents per bushel; which, as a bushel contains 45 dozen, is but 2 cents per dozen. (Ellsworth's Report, 1843.)

EGG-PLANT (Solanum melongene). This is a tender annual, a native of Africa. It loves a light rich soil, and blows violet flowers in June and July, which are succeeded by fruit, shaped and coloured like an egg. The plant is propagated by seed. In French and Italian cookery it is used in soups, and for the same purposes as the love-apple.

Two varieties of this annual plant are commonly met with in the United States; one of these bears a very large purple oval-shaped fruit, which is highly relished as a delicious and rich tasted vegetable. It is cooked by frying transverse sections or slices, and in other forms and ways. In size and shape the fruit resembles an ostrich egg, though it frequently attains a size many times larger, even to that of a small fruit. The water-melon. The second variety is white, and the shape bears a striking resemblance to the eggs of the domestic fowl. To raise them in the Middle and Northern States, the seed must be sown in a hot-bed in March, and transplanted into the open air as soon as there is no danger from frost, placing them about two feet apart. A pretty high degree of heat, blended with a good supply of moisture, are required to make the seeds germinate and bring forward the young plants.

The insane egg-plant (Solanum insanum). Mad-apple, or purple egg-plant, called by the French Aubergine rouge, is occasionally cultivated in the United States as a culinary vegetable. The whole plant is coated with a downy nap. The flowers are purplish and pendent, and the berries very large, ovoid-oblong, mostly of a dark purple colour when mature, and sometimes pale-green. (Flora Cestrica.)

EGLANTINE (Rosu rubiginosa; Fr. eglandin). The old English name of the sweetbrier rose. The odour which is so agreeable, is exhaled from reddish, viscid glands, which cover the
under surface of the leaflets. This odour enables it to be readily recognised from all our other wild roses, except the small-flowered sweetbrier (Ros a micranth a), which some believe to be only a variety of R. rubiginosa. The term eglantine is improperly applied by Milton to the honeysuckle.

ELETERS. See BEEFLE, SPRING-BEEFLE.

ELBOWS. A term applied to the shoulder-points of cattle.

ELDER (Sambucus nigra). It appears (says Phillips) that we have taken the word elder from elder, the French name of this tree. The common elder tree is a native of England, and is found also in most parts of Europe, as it will grow on any soil, and in situations where few other trees would thrive. The stem is much and oppositely branched; the branches being covered with a smooth, gray bark, and having a large spongy pith; the leaves consist of two pair of leaflets, with an odd one. The flowers are in cymes; the berries globular, deep purple. It may be observed, that our uncertain summer is established by the time the elder is in full flower, and entirely passed when its berries are ripe. An infusion of the leaves proves fatal to the various insects which thrive on blighted or delicate plants, nor do many of this tribe, in the caterpillar state, feed upon them. Cattle scarcely touch them, and the mole is driven away by their scent; but sheep eat the leaves greedily, and it is said to be a cure for the rot. The Rev. Mr. Parquharson, in an able paper in the Trans. High. Soc. vol. iv. p. 336, advocates the cultivation of the elder for hedges, from its rapidity of growth, hardihood, and cheapness. The only objection appears to be, that it does not thicken and close up its branches, so as to form an imperious fence, like the white thorn. M. Wehrle of Vienna has found, by a series of experiments, that the berries of the elder tree produce a much greater quantity of spirit than the best wheat. The spirit is obtained by pressing the berries, the juice of which is treated in the same way as the must of the grape, and afterwards distilled. If the results obtained by M. Wehrle are confirmed, it will be an additional motive for cultivating a plant which possesses many other useful qualities. (Quart. Journ. Agr. vol. iii. p. 183.) An odorous water is prepared by distilling the flowers; it is used as a perfume. The insipid juice of the berries is laxative and diuretic; and, mixed with water, forms a cooling beverage in fevers. The inner bark is purgative and emetic.

A correspondent of the New England Farmer says that the expressed juice of elder leaves will kill skippers in cheese, bacon, &c.; and strong decoctions of the leaves or roots are fatal to insects, which depredate on plants in gardens and fields. Dr. Willich observes, that the leaves of the elder are eaten by sheep, to which they are of great service when diseased with the rot; for if placed in a situation where they can easily reach the bark and young shoots, they will speedily cure themselves. Dr. Elliot observes in his Essay on Field Husbandry, that elder bushes are stubborn and hard to subdue, yet I know by experience, that mowing them five times a year will kill them. (N. E. Farmer.) Some persons have found a very effectual plan for destroying elders by taking a pole or staff and beating them down whilst in full blossom.

The species of elder most common in the United States, is called by botanists, Sambucus Canadensis. It is often a great nuisance along fence rows and hedges, where its straight stems attain a height of 5, 8, or 10 feet, being filled with a large pith. The flowers bloom in July and August, the peduncles spreading out so as to display the blossoms almost like an umbrella. The berries are very abundant, small, juicy, and dark purple, or nearly black when fully ripe. The long roots are very tenacious of life, and very much disposed to spread from lateral joints. The inner bark is a popular ingredient in making ointments for sores. An infusion of the bruised leaves is often used to expel insects from young cucumbers and other vines. The ripe berries, according to M. Cozens, afford a delicate re-agent, or chemical test, for detecting acids and alkalis. There is another species in the United States, called Sambucus pubens, which is found on the mountains in the north-eastern part of Pennsylvania. In this the flowers do not spread out like those of the common elder of the Middle States, but are crowded together so as to form dense ovoid heads or panicles. The berries are a scarlet red.

ELDER, BOX. In some parts of the United States, the name of box elder is popularly applied to the ash-leaved maple (Acer negundo). See M. Wehrle.

ELDER, THE WATER (Viburnum opulus). Commonly called Snow-ball. See GUILDER ROSE.

ELECAMPANE (Onula Helianthem). Called by the French Amsel. This is a plant with a perennial root and annual stem, which has been naturalized in the United States, where, in the old settled parts, it is frequent about houses, road-sides, &c., flowering in July and August. The stem or stalk is downy, and grows to the height of 3 to 6 feet, branching near the top. The leaves are long and large, with much down on the under surface. The flowers are large, and of a golden yellow. The roots, which constitute the medicinal part of the plant, should be dug up in autumn and in the second year of their growth, as when older they are apt to be stringy and woody. The dried root has a very peculiar and agreeable aromatic odour, slightly camphorous. The taste at first is glutinous and somewhat similar to that of rancid soap; upon chewing, it becomes warm, aromatic, and bitter. A peculiar principle, resembling starch, has been discovered in elecampane, by that distinguished German chemist, Rose, of Berlin, who named it alabun; but the term indulin is most generally adopted. It has been found in the roots of several other plants. In its medicinal properties elecampane is tonic and gently stimulant, &c. By the ancients it was much employed, especially in complaints peculiar to females. In the United States, its use is mostly confined to diseases of the lungs. It has also been extolled for its virtues when applied externally for the cure of itch, tetter, and other diseases of the skin.

ELECTRICITY. The application of this
science to the cultivation of the earth has hitherto not been very practically useful. Its operations—the very nature of electricity—are as yet much too little understood for the cultivator to derive instruction from its study. "Electrical changes," said Davy (Elements of Agr. Chem., p. 41), "are constantly taking place in nature on the surface of the earth, and in the atmosphere; but as yet the effects of this power in vegetation have not been correctly estimated. It has been shown, by experiments made by means of the voltaic battery (the instrument in which electricity is evolved by the mutual action of zinc, copper, and water), that compound bodies in general are capable of being decomposed by electrical powers; and it is probable, that the various electrical phenomena occurring in the vegetable kingdom must influence both the germination of seeds and the growth of plants. I found that corn sprouted much more rapidly in water positively electrified by the voltaic instrument, than in water negatively electrified; and experiments made upon the atmosphere show that clouds are usually negative; and as when a cloud is in one state of electricity, the surface of the earth beneath is brought into the opposite state, it is probable that, in common cases, the surface of the earth is negatively electrified. It is thus seen amongst scientific men respecting the nature of electricity: by some, the phenomena are conceived to depend upon a single subtle fluid, in excess in the bodies said to be positively electrified, in deficiency in the bodies said to be negatively electrified; a second class suppose the effects to be produced by two different fluids, called by them virutous and restrainous; and a third set regard them as affections, or motions of matter, and merely an exhibition of attractive powers, similar to those which produce chemical combination and decomposition, but usually exerting their action on masses."

ELEVATION, ATMOSPHERIC. The height of land above the sea or common level, exerts a very great influence upon the growth of plants. One of the main causes operating under such circumstances to diminish the size of plants, Professor Dobereiner believes to be the diminution of atmospheric pressure. Experiments have been made in order to prove this by placing seeds of barley in vessels, containing soil, water, and air, under different degrees of atmospheric pressure; and the result has been, that, where the pressure was greatest, the vigour of the plants was also greatest. See Altitude.

ELM (Ulmus). A genus of forest trees, common in Great Britain, of which there are several varieties. The characters of the genus are flowers, bisexual; only, bell-shaped, four to five toothed, coloured persistent; stamens, three to six; stigma, two, fruit, sub-globular, with a broad membranous margin. Sir James E. Smith (Eng. Flor, vol. ii. p. 19), describes five species of native elm:—viz. 1. The common small-leaved elm (U. campestris), which is found chiefly in the southern parts of England. The wood is hard and tough, particularly durable in wet situations, and is greatly preferred in Norfolk (where it is the most common species) to any other, and sells for nearly double the price, serving more especially for the naves of wheels. In other parts of England, and particularly about London, the wood of the common elm is used for coffins. 2. The common cork-barked elm (U. serotina), which is taller and more spreading than the foregoing. The bark when a year old is covered with very fine dense cork in deep fissures; whence the name. It is far inferior to the former in value. There are various cultivated varieties raised from seed. 3. The Dutch cork-barked elm (U. major); a doubtful native. The branches spread widely in a drooping manner, and the bark is rugged, much more corky than even the foregoing. Miller says this elm was brought from Holland in King William's reign, and being recommended for its quick growth, was a fashionable tree for hedges in gardens, but afterwards fell into disuse. He adds, that "the wood is good for nothing, so its use is almost banished in this country." 4. The broad-leaved Scotch elm, or wych hazel (U. montana). It is sometimes called the Hertfordshire elm, being very frequent and luxuriant in that county. The large hop-like fruit is abundant, and very conspicuous in May or June; and the seeds appear to be usually perfected. This is one of the most general species of elm in the British isles. It is a tree of quicker growth than the common small-leaved elm, and the wood is consequently far inferior in hardness and compactness, and more liable to split. The branches are in some individuals quite pendulous, like the weeping willow. The bark is smooth, and downy in a young state. 5. The smooth-leaved, or wych elm (U. glabra). A tall, elegant tree, with spreading, rather drooping, smooth, blackish branches, and smaller leaves than any of the preceding, except the first. The elm (says Brande) is valued for the rapidity of its growth, its hardness, and its capability of thriving in poor soil unfit for tillage. Tredgold (Princip. of Corp.), however, says the elm is of slow growth. The elms of England are scarcely less remarked for their age, bulk, and beauty than the British oaks. The colour of the heart-wood of elm is generally darker than that of oak, and of a redder brown. The sap wood is of a yellowish or brownish white, with pores inclined to red. It has a peculiar odour, is in general porous and coarse-grained—sometimes coarse-grained, and has no large septa. It twists and warps much in drying, and also shrinks considerably both in length and breadth. It is difficult to work, but not liable to split, and bears the driving of bolts and nails better than any other timber. What is known in Europe as the twisted elm (Urnem tortilil>d), is not a distinct species but only a variety of the European elm. The twisted form of the fibres is secured by culture, the young stalks being properly grafted and planted separately from the parent tree. In Scotland, chairs and other articles of household furniture are frequently made of elm wood; but in England, where the wood is inferior, besides the purposes already specified, it is chiefly in demand for the manufacture of casks, mill-wheels, pumps, water-pipes, axletrees, &c. It is appropriated to these purposes because of
its great durability in water, which also occasions its extensive use as piles and planking for wet foundations. A second-rate charcoal is made from this wood; and rails and gates of elm, thin sawed. Evelyn tells us in his System, are not so apt to rise as oak. Elm is said to bear train plants better than any other large tree. It is propagated by seed, layers, or suckers, and by grafting and budding. Suckers, however, generally disfigure those trees raised from layers or suckers. As the value of this timber consists more in the length and bulk of the shaft than in the irregular growth of its branches, it is the business of the planter to train them up tall and straight, and not to suffer them to branch till within a few feet of the top. The leaves of the elm are eagerly eaten by cattle, sheep, and hogs. The inner bark of the elm is nearly as valuable a medicinal agent as the mch-vaulted sarsaparilla. The decoction of it forms an excellent vehicle for minute doses of corrosive sublimate in some obstinate skin diseases; and in combination with vinegar or muriatic acid, it is a useful gargle in inflamed throats.

Several species of the Ulmus family are found in the United States. Among these the white or weeping elm (Ulmus americana), is met with over a very extensive tract of the continent. Michaux says that his father noticed it as high north as latitude 48° 20', near the entrance of the river Mistassin into Lake St. John, and that he had himself observed it from Nova Scotia to the extremity of Georgia, a distance of at least 1200 miles. It abounds in all the Western states. The district of country in which it seems to flourish best is comprised between the 42d and 46th degrees of latitude, in Western New York, the Eastern States, and adjoining British provinces. It delights in low and humid soils, and is frequently met with on the borders of swamps and fertile bottoms, associated with the white maple and buttonwood. On the banks of rivers its base is frequently overflowed by freshets, and its diameter often increases to four feet. But it is where the primitive forests, in which it has been once insulated, have been cleared away, that the American elm when left appears in its greatest majesty, towering to the height of 80 or 100 feet, with a trunk 4 or 5 feet in diameter, regularly shaped, naked, and insensibly diminishing to the height of 60 or 70 feet, where it divides into two or three primary limbs. These limbs do not part so suddenly as those of most other trees, but approach and cross each other, interlacing and bending their flexible branches so as to form regular arches of the Gothic character, floating lightly in the air. Michaux mentions a singularity in this tree he had found in no other, namely, that two small limbs, 4 or 5 feet long, grow in a reversed position near the first fork, and descend along the trunk.

The American white elm differs essentially from the red elm and the European elm in its flowers and seeds. The flowers appear before the leaves, and are very small and of a purple colour. The seeds are contained in a flat, oval, fringed capsule, being mature from the 15th of May to the 1st of June.

The buttonwood astonishes the eye by the size of its trunk and the amplitude of its head; but the white elm has a more majestic appearance, owing to its greater height, and the disposition of its principal limbs. When growing alone, the limbs generally branch off at 8, 10, or 12 feet from the ground.

"The trunk of this elm is covered with a white, tender bark, very deeply furrowed. The wood, like that of the common European elm, is of a dark brown, and, cut transversely or obliquely to the longitudinal fibres, it exhibits the same numerous and fine undulations; but it splits more easily, and has less compactness, hardness, and strength. This opinion was given me by several English wheelwrights established in the United States, and I have since proved its correctness by a comparison of the two species. The white elm is used, however, at New York and farther north, for the naves of coach-wheels, because it is difficult to procure the black gum, which at Philadelphia is preferred for this purpose. It is not admitted into the construction of houses or of vessels, except occasionally in the district of Maine for keels, for which it is adapted only by its size. Its bark is said to be easily detached during eight months of the year; soaked in water, and supplied by pounding, it is used in the Northern States for the bottoms of common chairs.

"Such are the few and unimportant uses of the white elm in the United States; it is far inferior to the European elm, which is a tree of very extensive utility, and it deserves attention in the old world only as the most magnificent vegetable of the temperate zone."

(Michaux.)

The Red or Tunwa elm (Ulmus rubra), called also the slippery elm.—"Except the maritime districts of the Carolinas and Georgia, this species of elm is found in all parts of the United States and of Canada. It bears the names of red elm, slippery elm, and Moose elm, of which the first is the most common; the French of Canada and Upper Louisiana call it Orme gras.

"The red elm, though not rare, is less common than the oaks, the maples, the sweet gum, and the sassafras; it is also less multiplied than the white elm, and the two species are rarely found together, as the red elm requires a substantial soil, free from moisture, and even delights in elevated and open situations, such as the steep banks of rivers, particularly of the Hudson and the Susquemanna. In Ohio, Kentucky, and Tennessee it is more multiplied than east of the mountains, and with the hickories, the wild cherry tree, the red mulberry, the sweet locust, the coffee tree, and some other species, it constitutes the growth upon the richest lands of an uneven surface.

"This tree is 50 or 60 feet high, and 15 or 20 inches in diameter. In the winter it is distinguished from the white elm by its buds, which are larger and rounder, and which, a fortnight before their development, are covered with a russet down.

"The flowers are aggregated at the extremity of the young shoots. The scales which surround the bunches of flowers are downy like the buds. The flowers and seeds differ from those of the preceding species; the calyx is downy and sessile, and the stamens are short
and of a pale rose colour; the seeds are larger, destitute of fringe, round, and very similar to those of the European elm; they are ripe towards the end of May. The leaves are oval-acuminately, doubly dentilicate, and larger, thicker, and rougher than those of the white elm.

"The bark upon the trunk is brown; the heart is coarser-grained and less compact than that of the white elm, and of a dull red tinge. I have remarked that the wood, even in branches of one or two inches in diameter, consists principally of perfect wood. This species is stronger, more durable when exposed to the weather, and of a better quality than the white elm; hence in the Western States it is employed with greater advantage in the construction of houses, and sometimes of boats on the banks of the Ohio. It is the best wood of the United States for blocks, and its scarcerness in the Atlantic States is the only cause of its limited consumption in the ports. It makes excellent rails, which are of long duration, and are formed with little labour, as the trunk divides itself easily and regularly; this is probably the reason that it is never employed for the naves of wheels.

"The red elm bears a strong likeness to a species or a variety in Europe known by the name of Dutch elm. The leaves and the bark of the branches, macerated in water, yield, like those of the Dutch elm, a thick and abundant mucilage, which is used for a refreshing drink in colds, and for emollient plasters in place of the marsh-mallow root, which does not grow in the United States.

"Though the red elm is superior to the white elm, it is not equal to our European species, and its culture cannot be generally recommended.

"Observation. In the district of Maine and on the banks of Lake Champlain I have found another elm, which I judged to be a distinct species. Its leaves were oval-acuminately, rough, and deeply whorled. I have never seen its flowers or its seeds. The length of its young shoots announced a vigorous vegetation. It is confounded in use with the white elm, to which it is perhaps superior; it is found in the nurseries of France, and probably it came originally from Canada." (Michaux.)

The red elm of the United States bears so strong a resemblance to the Dutch elm, both in foliage and fruit, that it is not always easy to tell them apart. The species of elm known in the South by the American name of Wahoo, is the Ulmus alata of Michaux. It is a stranger to the Northern and Middle States, and to the mountainous regions of the Alleghanies; being found almost exclusively in the lower part of Virginia, in the maritime districts of the Southern States, in West Tennessee, and in some parts of Kentucky. It prefers the banks of rivers and great swamps, and attains a middle size, commonly not rising higher than 30 feet, with a diameter of 9 or 10 inches. The branches of the wahoo are furnished throughout their whole breadth, with two opposite sides, with a fungous appearance, or fringe, two or three lines wide, from which the specific name, alata, winged, is derived. The wood is fine-grained, more compact, heavier and stronger than that of the American white elm. The heart is of a dull red, approaching to chocolate-colour, and always bears a large proportion to the sap. In those parts of the country where it grows, it is employed for coach-wheels, and is even preferred for this purpose to the black gum, as being more hard and tough.

Another American species of elm has been discovered by Mr. Nuttall, who calls it the Opaque-leaved elm. He found it in Arkansas, on the plains of the Red river, 1100 miles above its mouth, where it forms a majestic forest tree. It is distinguished for the smallness and thickness of its oblique and usually blunt leaves, which, with their short stalks, are only about an inch in length by half an inch in breadth, and very numerous. The taste of the plant is astrigent, and it is not mucilaginous.

Mr. Nuttall considers this remarkable tree to be nearly allied to the Chinese elm (Ulmus Chinensis). Of the uses and quality of its wood he does not speak. The density of shade produced by it, so crowded with rigid leaves, and the peculiarity of its appearance, he says, entitle it to a place in the nurseries of the curious, as he thinks it quite hardy enough for all temperate climates. To this species, he remarks, Virgill's epithet,"

"Facundae frondibus ulmi,"

might be more justly applied than to any other. (Nuttall's Spec. to Michaux.)

An American species called Thomas's elm (Ulmus racemosa), which has hitherto been confounded with other elms, is, according to Professor Torrey, abundant in the western part of the State of New York, and probably of the Western States generally. Mr. Thomas, its discoverer, found it in Cayuga county, New York, and the adjacent country. G. B. Emerson, Esq., says that specimens have also been obtained from Vermont, collected by Dr. Robbins, so that it is probably both a northern and western species.

The lowermost stout branches, according to Mr. Thomas, produce corky excrescences like the Wahoo elm. For a further description, see Eaton's North Amer. Botany; Stillman's Journal, vol. xix. p. 170, with a plate; Nuttall's Supplement, p. 37.

ELYMUS. The lime grass. A genus of large, rigid, or coarse grasses, mostly perennial, growing frequently on the sea-coast. Smith (Eng. Flora, vol. i. p. 177), describes three species. 1. Upright sea lime grass (E. arenarius). 2. Pendulous sea lime grass (E. geniculatus). 3. Wood lime grass (E. Europaeus). The last is found in woods, thickets, and hedges, on a chalky soil; herbage of a grassy green; stem erect, two feet high, and striated. As Sinclair has treated copiously of the proportional value of the different native and foreign species of Elymus, I shall follow his classification.

Elymus arenarius (Germ. Sand-haagreis, Pl. 7, o). Upright sea lime grass, stout, or bent, named from its upright, close spike. Its stalk is not winged, and the leaves are spinous, pointed. The calyx is lanceolate, the length of the spikelets. The nutritive matter afforded
ELYMUS.

by this lyme grass is remarkable for the large quantity of saccharine matter which it contains, amounting to more than one-third of its weight; this grass may, therefore, be considered as the sugar-cane of Britain. The saccharine matter must render the hay made from this grass very nutritious, particularly when cut into chaff, and mixed with corn or common hay. Its natural soil (if it can be called) is the sands of the sea-coast. This grass, when combined with the Avenula arenaria, seems admirably adapted by nature for the purpose of forming a barrier to the encroachment of the sea. The culms are very deficient, both on its natural soil and when cultivated. A greater proportion of saccharine matter is afforded by the culms of this grass than by the leaves. It flowers about the third week in July.

_Elymus geniculatus._ Knee-jointed or pendulous lyce grass. The stem is winged, and the spikes bent directly downwards. At the time of flowering, the produce from a sandy loam is 20,418 lbs. per acre. The foliage is tough and coarse, and the quantity of nutritive matter it affords is not considerable. The _Elymus arenaria_ is nearly allied to this species in its general habit; but differs specifically in the spikelets being pubescent, more compact, and the spike perfectly upright. The leaves are broader, the culms taller and stronger, and the root is more powerfully creeping. This species is greatly superior to the above in produce and nutritive properties, but neither appear to have merits sufficient to recommend it for cultivation; for even though both were early in the produce of fine foliage, and grew rapidly after being cut, their strong creeping roots, which exhaust the soil very much, would preclude their introduction on the farm. This species flowers in the second week in July, and the seed is perfected in about three weeks.

_Elymus hystrix._ Rough lyce grass. At the time of flowering, the produce from a rich, silicious, sandy loam was 27,225 lbs., of which half the weight is lost in drying. The nutritive matter afforded by the produce of an acre is only 1063 lbs. The harsh, broad, thin, light-green leaves of this species, and of those of the _E. geniculatus_ and _E. sibirica_, indicate that they are naturally inhabitants of woods, or wet, shady places. Grasses of this description are generally (indeed in every instance that has come under my observation) deficient in nutritive matter, and contain an excess of bitter extractive. Cattle appear to dislike these grasses. Oxen eat the Philadelphia lyce grass when it is offered to them, but they refuse the striated, Siberian, and rough lyce grasses. From the above details, there is no authority for recommending the rough lyce grass to the notice of the agriculturist. It flowers in the second week in July, and ripens the seed in about a month.

_Elymus Philadelphicus._ Philadelphia lyce grass. At the time of flowering, the green produce per acre from a clayey loam and retentive subsoil is 30,628 lbs., dry produce 15,314 lbs., nutritive matter, 2033 lbs.; so that it is a very productive grass, and contains a considerable quantity of nutritive matter. With respect to foliage, it is rather early in the spring. From the large size it attains, the produce is rank and proportionally coarse, and is unfit for pasture. It appears that for soiling, or hay to be used in the form of chaff, this and some other of the gigantic grasses would be profitable plants on soils unfit for the production of the superior pasture grasses, or of corn. A comparison of the quantity of nutritive matter contained in hay of the best quality with that made from this grass, will show nearly their comparative value. One pound of hay composed of the best natural grasses contains of nutritive matter 1276 lbs. of the very best of hay of the _E. Philadclphicus_ 34 drs. With regard to nutritive powers, therefore, five tons of the hay of this grass are scarcely equal to three tons of that of the superior grasses. But the soil that will produce this grass and others of the same class at the rate of six tons per acre, would not produce one-fifth the quantity of the superior grasses; consequently the adoption of the tall fescue and Philadelphia lyce grasses on soils of this description for the uses now described, might be found a profitable measure. This grass flowers in the first and second weeks of July, and successively till the end of summer. The seed ripens in about three weeks after the time of flowering.

_Elymus Sibiricus._ Siberian lyce grass. At the time of flowering, the produce per acre from a rich sandy soil is 16,333 lbs., dry produce 5,717 lbs., nutritive matter 574 lbs. The produce of this grass is very coarse, and the weight of the crop, therefore, though considerable, is comparatively of no value. It is a native of Siberia, and withstands the effects of the severest continued frost, but not sudden changes from frost to fine weather. It requires to be sown every year, and treated as an annual. It comes into flower the second season, about the second or third week in June, and continues to emit flowering culms till autumn. A light, rich, silicious soil appears to be best adapted to its growth.

_Elymus striatus._ Striated lyce grass. At the time of flowering, the green produce per acre of this grass from a clayey loam is 20,418 lbs., dry produce 8,263 lbs., nutritive matter 1276 lbs. From the above details, this species is inferior in nutritive powers to the Philadelphia lyce grass in the proportion of 17 to 16. It is also much later in the production of foliage in the spring, and does not come into flower till after that species has nearly perfected its seed. It cannot, therefore, be recommended for the purposes of the agriculturist. Flowers about the latter end of July, and ripens the seed in August. (Hort. Gram. Wob. p. 365—371.)

About eight American species of the lyce grass have been enumerated by botanists, found along streams or on the sea-shore, where, as in Europe, they often prove extremely useful in resisting the encroachment of the water. The Virginian lyce grass is sometimes called wild rye, although its spikes, like those of the Canadian lyce grass, more resemble at a little distance the heads of barley. It is a perennial, found along the banks of the Brandywine and in other parts of the Middle States, where it attains a height of three or four feet.
EMBANKMENT.

The Canadian lime grass is also a perennial, growing to a similar height with the species just mentioned, found in similar localities, and resembling it in most other respects, except in having its flowerets and their receptacle clothed with stiffish hairs. The variety glaucifolius of Torrey is generally a taller plant, with larger spikes, the awns long and somewhat curved, and the whole plant covered with a greenish-white or silvery appearance. It is found on the Schuykill, near Black Rock. The villous or hairy lime grass is a species also found on the banks of the Brandywine. The species called Porcupine lime grass (E. hystric), is remarkable for its expanded, bristly spike, somewhat resembling an apothecary's bottle-washer. It is a perennial, frequently found in the southern parts of Pennsylvania and other Middle States, in rich, moist, and rocky woodlands, where it flowers in July and ripens its seed in August. (See Flor. Cestric.)

EMBANKMENT. A large mound or bank of earth, thrown up for the purpose of protecting or reclaiming lands from being injured or inundated by the water of the sea, rivers, or lakes. Mr. P. Howard narrates in the Com. to the Board of Agr. vol. vi. p. 148, the methods in use for embankments abroad.

In Yorkshire, Lincolnshire, Cambridgeshire, and other places in England, many hundreds of thousands of acres have been taken up by embanking. In Holland, the whole country has in a great measure been gained in this way. Near Chester, the River Dee Company have also reclaimed some thousands of acres from the sea, which are now divided into several beautiful farms. Mr. A. W. Maddocks, of Carnarvon, enclosed 1080 acres from the sea, by an embankment of two miles in extent. (Ibid. vol. vi. p. 159.) Lord Boringdon also reclaimed a large tract of land from the sea by embanking. (Ibid. p. 255.) Mr. Vernershia, likewise describes (ibid. vol. vii. p. 59), the plan he pursued in taking in from the sea 100 acres of valuable carse land. In the Lib. of Useful Know., "Brit. Husb." vol. i. p. 447-449, will be found some excellent observations on the embankment of rivers, and the cost of an operation of the kind. In the Quart. Journ. of Agr. vol. viii. p. 377, will also be found some interesting details on the same subject.

There are many other parts of the United Kingdom in which capital might be advantageously employed for the same purpose. It is a question of even greater magnitude, and one on which, as in the proposed embankment of the Wash, may be carried in some districts to a much greater extent than is commonly supposed. It is an improvement which must be so much varied, according to the situation in which the farmer is placed, that it would be impossible, in this work, to go into engineering details; for, as Mr. Blackie remarks (Trans. of High. Soc. vol. ii. p. 745.), "It would be an Herculean task to attempt to lay down rules, or even to prescribe the best means of raising the requisite structures in every situation. So many local impediments occur, so many unlooked-for obstacles must be surmounted, and there are always so many circumstances to be attended to and provided for, that much must ever depend on the ingenuity and ability of the director." See also Rev. G. Hamilton, Mr. Sidney, and Mr. Macleod. (Ibid. p. 97-103; Johnstone on Draining and Embanking; and Stephens on Irrigation.)

EMROGATION (Gr. μυτήργας). In farriery, it is a liquid application, usually prepared of volatile and spiritsuous ingredients, chiefly used by friction to relieve pains, numbness, &c.

EMOLIENTS (Lat. emolliens). In farriery, such remedies as relax and diminish the hardness and rigidity of the parts to which they are applied.

ENCHANTER'S NIGHTSHADE (Circeae). Of this perennial herbaceous genus of plants there are two indigenous species, the common enchanter's nightshade (C. lutetiana), and the mountain enchanter's nightshade (C. alpina). The former grows in moist, shady places, hedge-bottoms, church-yards, orchards, &c.: the root is tenaciously creeping; the stem 18 or 20 inches high; round and branching; the leaves, of a darkish dull green, waved, with short teeth, one rib, and many veins; the flowers are in clusters, many, small, and scentless, white or reddish, with a brownish-green calyx; the fruit is a bur, clothed with hooked bristles. Two species of this plant are known in the United States. The one commonly found in moist, rich wood-lands in Pennsylvania and other Middle States, varies somewhat. Dr. Darlington says, from the circæa of Europe. (Flor. Cestric. and Eng. Flor. vol. i. p. 15.)

ENDIVE (Cicerorium endivium). This plant is too well known to require description. There are three varieties. The green-curled is the only one cultivated for the main crops. When the larger seedlings have been transplanted, the smaller ones which remain may be cleared of weeds, and have a gentle watering; by which treatment, in 12 or 14 days they will have filled out a good sized head and become a second successional crop; and by a repetition of this management, in general, a third. The plants are generally fit for transplanting when of a month's growth in the seed bed; but a more certain criterion is, that when 5 or 6 inches high, they are of the most favourable size. They must be set in rows 12 or 15 inches apart each way; the Batavian requires the greatest space. Some gardeners recommend them to be set in trenches or drills, 3 or 4 inches deep; this mode is not detrimental in summe and dry weather; but in winter, when every precaution is to be adopted for the prevention of decay, it is always injurious. About three months elapse between the time of sowing and the fitness of the plants for blanching. This operation, if conducted properly, will be completed in from ten to fourteen days in summer or in three or four weeks in winter. In hot weather, the blanching is completed in half the time that is required if the season is cold. To blanch the plants, it is the most common practice to tie the leaves together; to place tiles or pieces of board upon them, or to bury them with garden pots; whilst some recommend the leaves to be tied together, and then to be covered up to their tips with mould, making it rise to an apex, so as to throw off

ENTOMOLOGY. A term signifying the knowledge of insects. The importance of such knowledge to those interested in agriculture or rural affairs, must be obvious to every one who reflects upon the advantages derived from the useful labours of some insects, and the devastations committed by others. The first step in proof of the utility of this science, might be to show that insects do a great deal of harm. Besides wire-worms and other insects which eat the seed in the ground, and weevils which destroy the contents of the granaries, flies torment the domestic animal whilst alive and blow their flesh when dead. Caterpillars eat cabbages, and moths riddle holes in cloth. Cloth is destroyed by a small weevil (Apion flavipes); a Dutch clover by the Apion flavedo; peas in the pod by the small beetle (Bruchus granarius). The turnip-fly is properly a beetle—a little jumping beetle (Haltica nemorum).

The problem of course is, how to destroy this legion of enemies. Now to do this with the greatest effect, we must watch them through all their changes. There may probably be many persons ignorant that most insects pass through four stages of existence (of which the silkworm affords a familiar instance)—1. The egg; 2. The caterpillar; 3. The chrysalis; and, 4. The butterfly or imago. It is in the second stage that insects generally do the most mischief. In the egg and the chrysalis they do none; and in the imago, some do and some do not. Though we are all familiar with the insect in the shape in which its ravages compel our attention, we are frequently unconscious of its identity under other shapes. We look on the cockchafer, without suspecting that its issue is the grub which eats the roots of the grass. But however desirable a knowledge of entomology may be, no single individual could acquire it all for himself. He would need the eyes of Argus, the patience of Job, and the years of Methuselah. The diligence and sagacity of men who have passed their lives in this study have at length accumulated a body of facts of the highest value; being printed, they have become the property of everybody who will take the trouble to read them; and thus a school-boy may learn in a few months facts which the labours of his whole life might have been vainly exerted in seeking.

Messrs. Kirby and Spence in Europe, and Dr. Harris in America, are the great authorities upon this subject, and from their books most of the facts stated in this encyclopedia have been taken. They themselves suggest a similar application to practice of the truths of their favourite science. "With respect to noxious caterpillars in general," say they, "farmers and gardeners are not usually aware that the best mode of preventing their attacks is to destroy the female fly before she has laid her eggs; to do which, the moth proceeding from each must be first ascertained; but if their research were carried still farther, so as to enable them to distinguish the pupa, and discover its haunts (and it would not be difficult to detect that of the greatest pest of our gardens, the cabbage butterfly), the work might be still more effectually accomplished."

The process of destroying noxious insects by attacking them in their early stages is not new. P. Musgrave collected the chrysalids in the spring, so as to become acquainted with them, and then employed people to catch and kill the moths and butterflies. If you catch 200 in a day, you destroy 10,000 eggs, which would give 120,000 in a fortnight. Might not boys and girls be well employed in doing this? They have all the organ of destructiveness.

In short, it is abundantly evident, that if we knew them in all their changes, and know where they are concealed in autumn, winter, and spring, we might exterminate those multitudes which are now as the sands which are upon the sea-shore. And if not all the knowledge required be yet in our possession, a great deal is, and might be easily imparted to the young farmer, if we could catch him in his chrysalis state; and what little is still wanting would soon be accumulated when we had set so many keen and interested eyes to observe.
a fly could scarcely move but they would be watching him. (Farmer's Register.)

EPIDEMIC (Gr. ἐπί and ἐπίδημος; Fr. épidémique.)
In farriery, a term applied to such fevers, or other distempers of cattle, as attack great numbers at certain seasons, or any time, if many suffer in the same manner. The term is frequently confounded with infectious, which is perfectly distinct, and implies a disease communicated, not from the atmosphere, but from one individual to another. Horses are liable to epidemic fevers, and to several distempers of that kind, such as the epidemical catarrh or influenza, strangles, stagers, &c.

EPIDERMIS (Gr. ἐπίδερμα, the true skin.)
In botany, the exterior cellular coating of the bark, leaf, or stem of plants and trees. It is composed of cells compacted together into a stratum, varying in thickness in different species, and is often readily separable by gentle violence. It is believed to be intended by nature as a protection of the subjacent parts from the harmful effects of the atmosphere.

EPILEPSY (Gr. ἐπιλέπσης.) A disease which occurs in various animals. See SHEEP, DISEASES OF.

EREMACANUSIS (from ἔρημος, slow, and καναν, combustion.) A term applied in organic chemistry to denote one of the changes which vegetable and other organic matters undergo after death.

The conversion of wood into humus, the formation of acetic acid out of alcohol, nitrification, and numerous other processes, are of this nature. Vegetable juices of every kind, parts of animal and vegetable substances, moist sawdust, blood, &c., cannot be exposed to the air, without suffering immediately a progressive change of colour and properties, during which oxygen is absorbed. These changes do not take place when water is excluded, or when the substances are exposed to the temperature of 32°; and different bodies require different degrees of heat, in order to effect the absorption of oxygen, and, consequently, their eremacausis.
The property of suffering this change is possessed in the highest degree by substances which contain nitrogen.
The decay of woody fibre (the principal constituent in all plants) is accompanied by a phenomenon of a peculiar kind. This substance, in contact with air or oxygen gas, converts the latter into an equal volume of carbonic acid, and its decay ceases upon the disappearance of the oxygen. If the carbonic acid is removed, and oxygen replaced, its decay recommences, that is, it again converts oxygen into carbonic acid. Woody fibre consists of carbon and the elements of water; and if we judge only from the products formed during its decomposition, and from those formed by pure charcoal, burned at a high temperature, we might conclude that the causes were the same in both: the decay of woody fibre proceeds, therefore, as if no hydrogen or oxygen entered into its composition.

In the Appendix to the Third Report of the Agriculture of Massachusetts, 1840, Dr. S. L. Dana adduces the following example, to show that even a moist plant will not decay, if air is excluded. A piece of a white birch tree was taken from a depth of twenty-five feet below the surface, in Lowell. "It must have been inundated there probably before the creation of man, yet this most perishable of all wood is nearly as sound as if cut from the forest last fall."

A very long time is required for the completion of this process of combustion, and the presence of water is necessary for its maintenance; alkalis promote the process, and retard it; all antiseptic substances, such as sulphurous acid, the mercurial salts, empyreumatic oils, &c., cause its complete cessation.

Woody fibre, in a state of decay, is the substance called humus.
The property of woody fibre to convert surrounding oxygen gas into carbonic acid diminishes in proportion as its decay advances, and at last a certain quantity of a brown coaly-looking substance remains, in which this property is entirely wanting. This substance is called wood; it is the product of the complex decay of woody fibre. Mould constitutes the principal part of all the strata of brown coal and peat. (Liebig's Organic Chemistry.)
The eremacausis or purefaction of substances containing nitrogen, is the process technically called nitrification.

ERGOT (Spermatia clausa.) A parasitic fungus, which most frequently appears upon the ears of rye, but sometimes upon other plants of the gramineous order. It most commonly appears in hot, damp summers. It is known to be present by the change which the affected grains assume; but these seldom exceed five or six in an ear. The grain lengthens to more than double its natural size, becomes angled, of a deep purplish-brown colour, and curved at its apex, where the ergot is seated. The surface, when viewed through a magnifying glass, appears studded with transparent, shining, white, angular dots; and when sliced and viewed in water under the microscope, it is seen to consist of white, flocculent threads, bearing globular spores. The ergotized grains have a heavy, unpleasant odour, and an acrid, nauseous taste, leaving a slight sensation of heat in the palate. Ergotized rye is poisonous both to man and other animals. When, in bad seasons, it has prevailed, and has been ground into flour with the rye, and baked in bread, it has caused many fatal depopulating epidemics in the north of Europe. On quadrupeds its use is followed by emaciation, palsy of the hindlegs, and extreme debility; mules in South America lose their hoofs and hair when fed on ergotized maize; and hogs which have been rye mixed with their food, lay eggs without shells, owing to its excitement of the oviduct. It is employed as a medicine in difficult parturition, but it ought not to be administered without the greatest caution and discretion. (Edin. Med. and Surg. Journ. vol. lxxi.) See MILDEW.

ERICA VULGARIS. The common heath, ling, or heather. See HEATH.

ERIOPHORUM. The genus of cotton grasses, which see.

ERYNGO (Eryngium). A genus of plants consisting of eleven species, two of which are perennials, natives of England, viz., 1. The sea
ESCUENT.

holy, or sea eryngo (E. maritimum), which grows on the sandy sea-shore, where it strikes its long creeping roots eighteen or twenty feet deep into the soil; the radical leaves are more or less sheathing, stiff, spiny, three-lobed; it blows a bright blue flower in July or August. Stem a foot high; root whitish, of a pungent aromatic flavour, with a mixture of mucilage; herb smooth, glaucous, with an elegant blue tint. The roots, reckoned stimulating and restorative, are either sold candied or administered in decoctions variously prepared.

2. The field eryngo (E. campestris) grows on waste ground chiefly near the sea, and is not so common as the last. It is more bushy and slender, and of a paler glaucous green than the foregoing; radical leaves larger; flowers white or purplish. The leaves of both are somewhat sweet, and of a pungent flavour.

Mr. Nuttall notices five species of the eryngo or sea-holly, as found in the United States: 1. E. viride. 2. E. turgidum; 3. E. fistulum; 4. E. aquaturn. His general description of the foregoing is,—Stem rather low; leaves sword-shaped, distinctly margined with setose spines; setae frequently in pairs, &c.; flowers greenish-white.

5. E. graminea, without spines. This last was found in Florida by Dr. Baldwyn.

Many other species are sub-marine; some exist in inland depressions, and a considerable number grow in arid wastes. (Nuttall's Genera.)

ESCUENT (Lat. esculentus). A term applied to edible roots and plants, as carrots, turnips, cabbages, &c.

ESPAliERS (Fr. espalier), in horticulture, are trees trained by lattice-work or other supports on the borders of beds, or as hedges to enclose plots of ground. They may serve to defend in a great measure many tender plants from the inclemencies of wind and weather. The trees chiefly planted for espaliers are apples, pears, and plums. The principal objects aimed at, however, in espaliers, are to expose the foliage and fruit of the plants or trees more perfectly to the light and sun, to preserve the branches from being blown about by the winds, and to economize space by confining them within definite limits. (London's Sub. Gard. p. 232.)

ESPARCET. A local name for Sainfoin, which see.

ESTATE (Fr. estat), in common parlance, is applied to the landed property held by individuals; and a man is said to be of good or of small estate, according to the magnitude of his landed property. Estates vary exceedingly in size and value, in most parts of England. The largest estate in the kingdom may be worth 100,000l., or upwards, a year; and there are estates of most inferior degrees of magnitude, down to the annual value of 40s. In some counties the property is more, and in others it is less subdivided.

EUODIOMETER. The name of any apparatus or contrivance by which the purity of the air can be tested. It implies a measure of purity, and is chiefly employed to determine the proportion of oxygen which the air may contain.

EVAPORATION is the process by which substances in the fluid or other form are converted into vapour and steam. Ice, camphor, carbonate of ammonia, and many other solids evaporate readily in the open air. The evaporation of water is, however, the most interesting consideration in its relations to agriculture, as will be more particularly shown when treating of the evaporating qualities of soils, &c.

Water, when expanded into vapour, is highly elastic, and spreads itself by a force of its own. The amount of vapour existing at any time in a given place is determined by the degree of heat present. According, therefore, to the temperature of the water from which the vapour emanates, will be the elastic force and density of the vapour, provided the process be carried on in an open vessel.

The pressure of the air and of other vapours upon the surface of water in an open vessel, does not prevent evaporation of the liquid; it merely retards its progress. Experience shows that the space filled with an elastic fluid, as air or water, of another gaseous body, is capable of receiving as much gaseous vapour as if it were rapidly, only the repletion of that space with the vapour proceeds more slowly in the former predicament than in the latter, but in both cases it arrives eventually at the same pitch. Dr. Dalton has very ingeniously proved, that the particles of aeriform bodies present no permanent obstacle to the introduction of a gaseous atmosphere of another kind among them, but merely obstruct its diffusion momentarily, as if by a species of friction. Hence, evaporation at atmospheric temperatures is promoted by the mechanical diffusion of the vapours through the air with ventilating fans or chimney draughts; though, under brisk ebullition, the force of the steam readily overcomes that mechanical obstruction.

The atmosphere has seldom as much watery vapour as it is capable of holding, and therefore the process of evaporation is almost always going on wherever there is a source of moisture present. Under certain circumstances, however, evaporation is checked and even suspended. Suppose the temperature of the water to be midway between freezing and boiling, viz., 122° Fahrenheit; also, that the air in contact with it be of the same temperature, but filled with moisture, so that its interstitial spaces are full of vapour of corresponding elasticity with that given off by the water; it is certain that, under such circumstances, no fresh formation of vapour could take place. The air would then be said to be saturated, as it is at times when clothes hung out at common temperatures remain without drying, and the grass, leaves, and grain remain soaked in moisture. But the moment a portion of vapour escapes, or is drawn off by condensation into dew, cloud, rain, &c., an equivalent portion of vapour will immediately be enabled to rise, and the process of exhalation or evaporation recommences. The water exhaled at low temperatures, that is to say, below the boiling point, is commonly called vapour. When the temperature of fresh water in an open vessel, at or near the common level of the sea or tide-water, rises to 212° Fahrenheit, the water begins to boil and evaporate with exceeding rapidity, producing what is commonly termed steam.

447
EVAPORATION.

In such case the evaporation takes place, not only from the surface, but from every point in the interior of the vessel. This indicates that the evaporating force of the water gained from the increase of heat has become greater than the pressure of the atmosphere, which is sufficient to sustain a column of mercury thirty inches high in the barometer. If the pressure of the atmosphere be removed by the air-pump, the turbulent evaporation or boiling of water will take place at a much lower temperature than 212°, even down to the freezing point. But under the common pressure of the atmosphere, and below the temperature at which water boils, evaporation goes on quietly and slowly. In deep mines, which descend below the level of the sea, water requires a greater heat than 212° to make it boil. But on high mountains, or districts rising far above the level of the sea, the pressure of the air is lessened, and boiling takes place, as in the air-pump, at lower degrees.

The vapours exhaled from a liquid at any temperature contain more heat than the fluid from which they sprung; and they cease to form whenever the supply of heat into the liquid is stopped. Nevertheless, a thermometer held in the steam proceeding from hot water rises no higher than when placed in the water itself. The additional heat, therefore, contained by the vapour, is in a latent or concealed state, and does not become sensible to the thermometer until the vapour condenses. Any quantity of water requires, for its conversion into vapour or steam, five and a half times as much heat as is sufficient to heat it from the freezing point of 32° to the boiling point of 212°. The quantity of heat absorbed by one volume of water in its conversion into steam, is about 1000° Fahrenheit; it would be adequate to heat 1000 volumes of water one degree of the same scale; or to raise one volume of boiling water, confined in a non-conducting vessel, to 1180°. Were the vessel, charged with water so heated, opened, it would be instantly emptied by vaporization, since the whole caloric equivalent to its constitution as steam is present. When, upon the other hand, steam is condensed by contact with cold substances, so much heat is set free as is capable of heating five and a half times its weight of water, from 32° to 212° Fahrenheit. If the supply of heat to a copper be uniform, five hours and a half will be required to drive off its water in steam, provided one hour was taken in heating the water from the freezing to the boiling point, under the atmospheric pressure.

It thus appears that evaporation is a cooling process, because the water is obliged to take up an additional supply of heat to expand and keep it in a state of invisible vapour. It is equally plain, that when vapour is condensed into mist, cloud, dew, rain, snow, and ice, it must give out that extra supply of heat required to convert it into water. Hence, its contained and mild weather, evaporation is a cooling process, whilst in winter the condensation of vapour and congelation of water must tend to prevent more excessive cold, by throwing out latent heat into the atmosphere. The 1000 degrees of heat absorbed by watery vapour on its expansion into vapour, must of necessity be set free on its condensation and conversion into water.

EVERLASTING-PEA, BROAD-LEAVED (Lathyrus latifolius). A perennial plant of the vetch kind, which grows naturally in some places; it is easily cultivated, and annually yields a great burden of excellent provender, and might be cultivated to advantage as a green food for cattle, on any of the more strong sorts of soil. See VETCH and VETCHLING.

EVERLASTING, PEARLY (Gnaphalium marginatum). One of the names of the American cudweed. See CUDWEED.

EVER-YEAR'S-LAND. Such lands as have been cropped with a brown and white crop, or pulse and grain in alternation, for a length of time, without any intervening fallow. There are extensive common fields in Gloucestershire and other parts of England, which have been conducted under this management for perhaps centuries past.

EXOTICS (Gr. ἔξωτος, foreign). In gardening, a name given to plants which are not natives, but have been introduced from some other country.

EXTRACTS (Fr. Extraits; Ger. Extracten). The older apothecaries used this term to designate the product of the evaporation of any vegetable juice, infusion, or decoction; whether the latter two were made with water, alcohol, or ether; whence arose the distinction of aqueous, alcoholic, and ethereal extracts.

Fourcroy made many researches upon these preparations, and supposed that they had all a common basis, which he called the extractive principle. But Chevreul and other chemists have since proved that this pretended principle is a heterogeneous and very variable compound. By the term extract, therefore, is now meant merely the whole of the soluble matters obtained from vegetables, reduced by careful evaporation to either a pasty or solid consistence. The watery extracts, which are those most commonly made, are as various as the vegetables which yield them; some containing chiefly sugar or gum in great abundance, and are therefore innocent or inert; while others contain very energetic impregnations. The conduct of the evaporating heat is the capital point in the preparation of extracts. They should be always prepared, if possible, from the juice of the fresh plant, by subjecting its leaves or other succulent part, to the action of a powerful screw or hydraulic press; and the evaporation should be effected by the warmth of a water-bath, heated not beyond 100° or 120° Fahrenheit. Steam heat may perhaps be applied advantageously in some cases, where it is not likely to decompose any of the principles of the plant. But by far the best process for making extracts is in vacuo, upon the principles involved in the process of evaporation.

For therapeutic purposes, the concentration may be performed in the cold, by placing saucers filled with the expressed juice over a basin containing sulphuric acid, putting a glass receiver over them and exhausting its air.

EXUVLE (Lat.). The cast-off parts or co-
tering of animals, and also the shells and other marine productions met with in the bowels of the earth, having been deposited there for a vast length of time. The lobster casts his shell, the toad and snake shed their skin periodically, leeches and fishes seem to cast off euvial layers of mucus only; but in most reptiles the epithem is periodically moulted, either entire or in large coherent masses. The periodically moulted feathers of birds, and hairs of various species of mammalia, may also be regarded as euvial. Substances of these kinds, where they can be procured in sufficient quantities, are highly valuable as manures, and capable of extensive application, especially on all the clay soils.

EYE (Sax. eye; Ice. eiza). In the management of fruit-trees, implies the germ, small bud, or shoot inserted into a tree.

EYE-BRIGHT (Euphrasia officinalis). An elegant plant, indigenous to England, very common in mountainous pastures and dry heaths, varying in height from one to six inches. It flowers from July to September; its stalk is square and hard; the leaves of a bright green, flat, broad, and indented at the edges. The flowers are small and white, streaked and spotted with dark colours. On the mountains of Scotland there is a more slender variety, with smaller but more richly tinted blossoms; on the Alps a dwarf, large-flowered, more purply varied species is common. It must be gathered about September, when it has done flowering. The distilled water is spoken of by the old herbalists as a true eye-wort to strengthen and improve the sight. This reputation gave it the name of eye-bright, but, like many other ancient opinions respecting the virtues of plants, the value of the reputation is worn out. The eye-bright will not grow in gardens; it loves to hide itself in grass or heath, and will not thrive unless it is surrounded by plants that are taller than itself. It is eaten by cattle and sheep, but refused by hogs. (Eng. Flora, vol. iii. p. 125.)

Two herbs are known in the United States by this popular name. One is the Hypericurn-leaved Euphorbia (Euphorbia hypericifolia), a milky annual plant common in pastures and on road-sides. The juice applied to the eye causes severe smarting. The severe salivation to which grazing horses are subject is said to be caused by their eating this species of Euphorbia.

The other plant also sometimes called eye-bright, is the Indian tobacco, or Lobelia inflata, a biennial found abundantly in pastures, or road-sides, &c., flowering in July and August, and ripening its seeds in August and October. This plant is possessed of highly acrimonious properties, and is an active emetic, cathartic, and narcotic. These properties render it capable of doing much harm or good according to the judgment and discrimination with which it is employed in different diseases and the proper stages. Without such attention, and in the hands of ignorant professed quacks and rash pretenders, the indiscriminate use of this potent herb has been fraught with serious injury to the constitution, and not unfrequently with death more or less speedy.

FACTOR (Lat. factor; Fr. facteur). In mercantile law, an agent who is instructed with the property of others, which he is commissioned to dispose of. In Scotland the word factor is used synonymously with steward in England, signifying one who has the overlooking or management of an estate or a farm for another person.

FAGOT (Welsh fagot; Fr. fagot). A bundle of small cut wood tied together closely for fuel or other purposes. They are made up from the cuttings or thinnings of coppices or hedges; and, in many districts, are sold to the bakers.

FAIR (Old Fr. fere; Lat. ferre or form). A public place where merchants, traders, and other persons assemble from remote parts on some fixed day in the year to buy and sell commodities, and to partake of the diversions usually to be met with on such occasions. See MARKET. Fairs and markets are very closely allied. A fair, as the term is now generally understood, is only a greater species of market recurring at more distant intervals. Both are appropriated to the sale of one or more kinds of goods, the hiring of servants or labourers, &c.; but fairs are generally attended by a greater concourse of people, for whose amusement various exhibitions are got up.

Fairs originated in England in monkish days, when proud bishops and mitred abbots were not unwilling to increase their revenues by the tolls which they were empowered by royal charter to levy on the crowds who commonly attended the festivals of their patron saints. Spreading rumours with an intent to increase the price at fairs or markets is in England an offence at common law. (Rex v. Haddington, 1 East, 148.)

Various statutes have been passed to regulate fairs.—By the 2 & 3 P. and M. c. 7, the owner or keeper of every fair must appoint a certain open place for the sale of horses, and must, under a penalty of 40 shillings, appoint some one to attend to take toll, from 10 A. M. till sunset; must keep a book, and enter there in the marks, price, colour, &c., seller's and buyer's name and residence, or forfeit 40 shillings.—By the 31 Eliz. c. 12, if the parties are strangers to the book-keeper, they must procure a person to vouch for them; his fee for
Fallows have different names given to them, and are of different kinds, according to the purposes for which they are intended, and the manner in which they are made. Thus, a 

**naked fallow** is that in which the ground is ploughed and harrowed at suitable intervals for several successive times, according to the kind of crop that is ultimately to be grown, but without being sown till it has remained in fallow for some length of time. A **green fallow** is that where the land has been rendered mellow and clear from weeds by means of some kind of green crop, such as turnips, peas, tares, potatoes, &c. In this mode of fallowing, no time is lost by the land being left idle, or in an unproductive state. Fallows are also sometimes distinguished by the season of the year in which the business is chiefly or wholly performed, hence we have **summer** and **winter** fallows; and likewise from their being in some cases only done in a partial manner, we have **bastard** fallows. Fallows are also named after the particular crops, as wheat, turnip, and potato fallows.

"The chemical theory of fallowing," observes Sir H. Davy (Elem. of Agr. Chem. p. 23), "is very simple; fallowing affords no new source of riches to the soil, it merely tends to produce an accumulation of decomposing matter, which, in the common course of crops, would be employed as it is formed; and it is scarcely possible to imagine a single instance of a cultivated soil, which can be supposed to remain fallow for a year with advantage to the farmer; the only case where this practice is beneficial seems to be in the destruction of weeds, and for cleansing foul soils." It has been indeed recently contended by Liebig in his *Organic Chemistry*, that during a fallow, a quantity of ammonia is collected from the atmosphere, potash disengaged from its combinations, and other chemical effects produced, which it is hardly necessary to examine at much length. He says (Organic Chem. p. 150),

"The fallow time is that period of culture, during which land is exposed to a progressive disintegration by means of the influence of the atmosphere, for the purpose of rendering a certain quantity of alkalies capable of being appropriated by plants. Now it is evident, that the careful tilling of fallow land must increase and accelerate this disintegration. For the purpose of agriculture, it is quite indifferent whether the land is covered with weeds, or with a plant which does not abstract the potash enclosed in it. Now many plants of the family of the Leguminosae are remarkable on account of the small quantity of alkalies or salts in general which they contain; the *Vicia faba*, for example, contains no free alkalies, and not one per cent. of the phosphates of lime and magnesia. The bean of the *Phaseolus vulgaris* contains only traces of salts. The stem of the *Medicago sativa* contains only 0.83 per cent. of that of the *Eremum tenus* only 0.57 per cent. of phosphates of lime, with albumen. Buckwheat dried in the sun yields only 0.68 per cent. of ashes, and all their soluble salts. Some plants belong to those which are termed fallow crops, and the cause why they do not exercise any injurious in-
fluence on corn which is cultivated immediately after them is, that they do not extract the alkalies of the soil, and only a very small quantity of phosphates."

**FAN.** See **WINDING MACHINE.**

**FAR (Six. reop.)** In horsemanship, a term used to denote a horse's right side; thus the far foot, far shoulder, &c. is the right foot, right shoulder, &c.

**FARCY.** In farriery, a disease of the abscesses affecting the skin and its blood-vessels, by which, when inveeterate, their coats inflame and are so thickened that they become like so many cords. Farcy is intimately connected with glanders, and they will frequently run into each other. The treatment varies with the form it assumes. In the button, or bud farcy, in which indolent boils appear, a mild dose of physic should be first administered. The buds should then be carefully examined, and, if any of them have broken, the building iron, of a dull red heat, should be applied to them, and the buds all opened as soon as they appear to contain matter, and afterwards washed with a lotion composed of a drachm of corrosive sublimate, dissolved in an ounce of rectified spirit. Daily exercise and green food are also essential to the animal's recovery.

**FARCY, WATER.** See **DROPSY.**

**FARDING-BAG.** The first stomach of a cow, or any other ruminant animal. It is a mere receptacle for receiving and retaining the green food, until the animal has time to repose and chew the cud.

**FARINA (Lat. far, corn, of which it is made).** Meal or flour obtained by grinding and sifting wheat and other seeds, or by pulverizing and preparing edible roots, &c.; hence the term farinaceous food.

**FARM.** A portion of ground cultivated for the purpose of profit. There are different kinds of farms according to the kind of crop or the use for which the produce is intended. Where the principal part of the land is under the plough, they are termed arable farms; but where the fattening of cattle or other live-stock is more immediately the object, they are distinguished by the title of grazing farms; where the chief intention is the obtaining different animal products, such as milk, butter, and cheese, they are denominated dairy farms; and where the two systems of arable and grass management can be combined, they are called convertible farms. As manure must be had in order to render farms of any kind productive, the last may probably, in general, be considered as the most advantageous. Besides these, in districts where hay is the principal produce, there are hay or grass farms, and there are also what are denominated breeding or cattle farms.

The old writers on husbandry, who lived in warm countries, where the heat and moisture of the air had sensible and frequently very dangerous effects on the health of the inhabitants, were very particular in their directions for the choice of farms or estates, and of the spots whereon houses should be built, so as to avoid the inconveniences arising from the climate, or from the quality or situation of the ground. The Romans had generally pleasure as well as profit in view, when they bought and stocked a farm; and therefore they laid it down as a rule, that no degree of fertility should tempt a man to purchase in an unhealthy country, nor the pleasantest situations in a barren one. "Buy not too hastily," said Cato, "but view again and again the purchase you intend to make; for, if it be a good one, the oftener you see it the better it will please you. Examining the several points of a farm, it is to be observed that you should "the way to and from it good; and the air temperate. Let your land, if you can choose your situation, be at the foot of a hill, facing the south, in a healthy place where a sufficiency of labourers, of cattle, and of water may be had. Let it be near a flourishing town, the sea, or a navigable river; or bordering upon a good and well-frequented road. Let the buildings upon your ground be strong and substantial. Do not rashly condemn the methods of others. It is best to purchase from a good husbandman and a good improver."

Besides the healthfulness of the situation, three other things should be particularly attended to in the choice of a farm or estate; these are, the air, the water, and the soil. The air should be pure and temperate, the water wholesome and easily come at, and the soil fertile; and the farm should be at a reasonable distance from good markets, both for the sale of the produce and the purchase of manure.

See **FARM BUILDINGS.**

The ancients were particularly attentive to the quality of their water, and to the ease of coming at it. They advised bringing into the farm-houses the water of such springs as never dried up; or, if there was no such spring within the farm, to bring running water as near to it as possible; or to dig for well-water, not of a bitter or brackish taste. If neither of these was to be found, they directed large cisterns to be provided for men, and ponds for cattle, for collecting rain water. They esteemed that running water to be best for drinking which had its source in a hill; spring or well-water from a rising ground was deemed the next best; well-water in the bottom of a valley was held to be suspicious; and marshy or fenny water, which creeps slowly on, was by them rightly regarded as the worst of all.

The nature of the soil of a farm may be ascertained either by analysis (see **ANALYSIS**), by observation of the weeds which flourish upon it (see **BOTANY and WEEDS**), and of the trees growing in the hedge rows (see **PLANTATIONS**). In England the elm and the oak are commonly tenants of good soils; the birch, the holly, and the ash indicate those which are poor. And again, the productiveness of a soil may be estimated from the degree of its attraction for the insensible moisture of the atmosphere; by the substratum on which it rests (see **GEOLOGY**); and by its inclination. There are many other circumstances, also, which the farmer in search of a farm should regard, most of which he will find treated of in this work under the heads **APPRAISMENT, AGREEMENT, CUSTOMS OF COUNTIES, CAPITAL REQUIREMENT, RAIN, LEASE, &C.** Let him also closely examine the state of the buildings, the mode in which the farm has been cultivated, and the
FARM ACCOUNTS.

The number of farms in the United Kingdom is estimated to be about 2,000,000, and the property annually derived from agriculture at 215,817,624L.

In England and Wales it is calculated that there are 2,350,000 acres employed in wheat.

FARM ACCOUNTS. The necessity and utility of correct and detailed particulars of all matters concerning the farm, have already been spoken of under the head Book-keeping. Let any farmer make the experiment, and he will find it both interesting and useful, to know from year to year the actual products of his farm. Let every thing, therefore, which can be measured and weighed, be so tested; and let that which cannot be brought to an exact standard be estimated, as if he himself were about to sell or to purchase it. Let him likewise, as near as possible, measure the ground which he plants, the quantity of seed which he uses, and the manure which he applies. The labour of doing this is nothing compared with the satisfaction of having done it, and the benefits which must arise from it. Conjecture, in these cases, is perfectly wild and uncertain—varying often, with different individuals, almost 100 per cent. Exactness enables a man to form conclusions which may most essentially, and in innumerable ways, avail to his advantage. It is that alone which can give any value to his experience; it is that which will make his experience the sure basis of improvement; it will put it in his power to give safe counsel to his friends; and it is the only ground on which he can securely place confidence in himself.

FARM BUILDINGS. In the construction of farm buildings, the first thing to be regarded is the convenience of their situation; and to this end must be considered the best shelter, feeding and watering of live-stock; the carriage of the crop, and of manure, and the preservation of the produce. To combine all these advantage together is rarely attainable; the object with the practical farmer is to obtain as many of them as possible. The improved economical construction of farm buildings some years since engaged the attention of the Highland Society in Scotland, and from their report (Trans. vol. ii. p. 365), the reader who wishes for working plans will derive abundant information. The committee say, very justly, "one of the most common errors in these designs is the crowding the buildings together, under the idea of giving them greater compactness, and the not sufficiently extending the shelter sheds for the feeding of cattle. This is a fault so universal that it is only on the larger class of breeding and feeding farms in the border counties of England and Scotland that experience has taught builders fully to avoid it. In giving designs of the outouses of a farm, little more can be done than to give general useful examples. Although a certain similarity must exist in the form and arrangement of the parts of all such buildings, yet these must be modified according to the circumstances of the farm itself, the character of the soil, the means which the owner will provide, and the particular kind of management to be pursued. No one rule that can be given is of general application, and the judgment of the architect must be shown, in adapting the size, form, and arrangements of the buildings to the nature of the farm, and the wants of the occupier. While every suitable accommodation should be afforded to the tenant, it is the province of the architect to take care that the heavy cost of such buildings be not unnecessarily enhanced, either by erecting buildings that are useless, or by giving unnecessary dimensions to such as are requisite. It may be particularly remarked that the giving unnecessary breadth to the buildings adds materially to the expense, by increasing the dimensions of the timbers, and adding to the size of the roofs. At the same time care must be taken that in the cow-houses and stables the animals shall not be cramped from the want of necessary room. In general, it may be said that the most convenient arrangement of the outhouses of a farm is in the form of a rectangle, the side to the south being open, and the farm-house being placed at some convenient distance in front of it. And again, the most approved mode of keeping and feeding the larger and finer kinds of cattle is in small sheds with open yards attached, each capable of holding two animals. It is recommended that the water-course from the stables, cow-houses, and yards should be carried off by canals and open channels to a pond or tank near to the buildings. This mode of conveying away and receiving the urine is conceived to be better in ordinary cases than sewers below ground, which, even when executed in the best manner, will be subject to be choked up from want of necessary attention to cleaning; and such sewers become nurseries for rats, notwithstanding every precaution that can be taken. Should the situation of the buildings incline to the north, conduits can be made through the north range below the floors, at proper places, for discharging the liquids.

"For watering cattle, if a stream cannot be
obtained, there are few situations where water cannot be got by sinking a well; the best way is to raise it into a cistern, which may be placed in any of the sheltered yards, and from this be conveyed by pipes to the different yards, furnished with proper cisterns and ball-cocks. The passages and entrances to the buildings should be wide; the gates hung on wooden posts or hewn stone pillars.

**FARMER.**

1. the easy and Calculating to sessors proprietors quire ranged Flanders healthy wholesome to generally posts they The nant stagnant. vegetable dry pools, selected or be raise percolate, and farmers, according to the modes in which their farms are cultivated or employed.

The farmers of Great Britain, who are generally men of superior intelligence to those of Flanders or other parts of Europe, may be arranged into the following classes: 1. The great proprietors and country gentlemen. 2. Yeomen and farmers, properly so called. 3. Possessors of small farms. 4. Cottagers, including different descriptions of people, who cultivate small farms, and a few acres adjoining to towns and villages.

**FARM-HOUSE.** The dwelling occupied by a farmer. The principal objects to be attended to in erecting a farm-house are, convenience and a salubrious situation. Besides the general salubrity of the spot where dwellings are to be erected, the air, water, and soil also require to be particularly attended to: the first should be pure and temperate; the second wholesome and easily obtained. The most healthy and convenient site on the farm ought to be selected for building the house; easy access and central situation being taken into consideration. An abundant supply of water for domestic purposes, and for live-stock, is indispensable. The water, however, should not be stagnant. Ponds in the immediate vicinity of a house are not essentially injurious, unless they are of a stagnant state or of a muddy and stagnant nature; for at the period between the drying up and the complete dryness of ponds, or stagnant pools, the decomposition of animal and vegetable matter which is then proceeding evolves miasmata that generate disease. A dry gravelly soil, through which the rain can freely percolate, is to be preferred. The degree of dampness of a locality may be always pretty correctly estimated by observing the quantity of moss and lichens upon the trees; and the weeds being those that grow in marshy situations.

**FARMING.** The business or management of a farm, comprehending the whole circumstances and conduct of it. It is a practice that demands constant care and attention, as well as much activity and judgment, to conduct it in a proper and advantageous manner. It requires an intimate and practical knowledge of all the arts of cultivation and management, as well as of the nature and value of every kind of live-stock; and still further, a perfect acquaintance with the various modes of buying and selling, and the constant state of different markets and fairs. In addition to all these, there are several other minute of much consequence to the success of the farmer, which will be treated of under their respective heads.

**Farming,** once regarded as a profession easy to be understood and successfully followed only by the empiric, has long since been viewed in a different, in a wiser manner. It has been justly said that no pursuit requires more talent, perseverance, and more careful observation, than the cultivation of the earth; that so far from its being an empirical business, it is, in fact, one that several other sciences illustrate and assist—one, whose professors cannot too often examine the practice of other cultivators; and hence, since it has been found that the labourers of the chemist, the botanist, the mechanist, and the geologist, are all available in the service of the farmer, it has followed as a natural consequence, that the farmers of our age have become a more scientific, more educated, and a far more enlightened class than those of any previous generation.

**FARMS, OLD AND NEW.** Whether it is more profitable in the United States, to lay out money in the purchase and improvement of exhausted farms, or in the clearing and improvement of new land, is a question which requires more mature consideration than has been generally given to it. Calculations embracing the several expenses required in the two operations would seem to show, that the intelligent farmer, versed in the various processes of agriculture, who shall profit by the advantage of green fallow crops, will lay out his means most profitably in restoring worn-out land to fertility; provided he does not commit the common error of endeavouring to improve more land than his resources will enable him to do justice by.

On the other hand, the man of more limited means, who cannot buy an old farm or get one on a sufficiently long lease, may, by going west, purchase land at $1.25 per acre, or 200 acres for $250, which will be already in the highest state of fertility; those who are furnished with heavy timber or other natural beatment. This he clears and brings under cultivation little by little, working, perhaps, a certain portion of his time for others, in order to obtain subsistence previous to the coming in of his crops. Every acre cleared may cost him some 15 or 20 dollars, which, however, adds the same amount to the value of the farm, whilst every bushel of grain and every addition to his stock is so much gained. It may be several years before the pioneer will accumulate much property. Still, however, the prospect of an ultimate independence thus held out to the poor and industrious settler, is a good one.

He who has the advantage of sufficient means to enable him to purchase exhausted lands at from 5 to 10, 20, and even 30 or 40 dollars per acre, may, by a judicious application of lime, marl, plaster, and other mineral fertilizers, aided by green fallow crops ploughed under to form a mould, soon resuscitate a farm and render it producing magnific and take it valuable. The following facts will demonstrate the practicability of what is here asserted. More
instances could be produced, but this, being on unquestionable authority, is ample for present illustration.

Mr. George W. Cummins, of Smyrna, Delaware, purchased a farm near that place, containing about 200 acres. The land had been under cultivation for half a century or more, and its soil so completely exhausted as not to be capable of compensating for the labour and seed expended upon crops. It had, nevertheless, been rented, up to the time of purchase, and one of the conditions was the payment, annually, of two-fifths of the Indian corn crop. From a thirty acre field, the rent paid the last year was only about 30 bushels! Clover refused to grow upon this land, and wheat would not yield much more than the seed sown.

The soil was a sandy loam. The first step taken by Mr. Cummins for the restoration of this land to fertility, was, to sow one bushel of ground plaster per acre, flush it up in the spring, and spread upon it 70 bushels of slaked lime per acre. Oats were then sown at the rate of 2 or 3 bushels to the acre, and in July, when nearly fit for harvest, the straw being partly yellow and partly green, they were ploughed under. An ox-chain having been rigged in front of the coulter, so as to turn them down before the plough. Previous to this ploughing, 1¼ bushel more of ground plaster of Paris was sprinkled upon the ground. A second crop of oats sprung up in a thick mat from those ploughed under, and about the first of October, these were turned down by the plough like the first growth. Wheat was then sown, about 1½ bushel to the acre, and harrowed in, followed by clover early in the spring. The crop of wheat averaged about 8 bushels to the acre, and this, it will be observed, without a shovel-full of stable or other kind of animal manure. The clover had a bushel of ground plaster sprinkled upon it in the spring, and yielded the second season of its growth, about a ton per acre at the first mowing. Thus, land from which the vegetable mould had been entirely exhausted was, in a comparatively short time, and without the assistance of barn-yard or any other kind of animal manure, brought into a condition to yield compensating crops of wheat, corn, and vigorous clover. By the assistance of the ordinary quantity of barn-yard manure, the produce of wheat would average about 25 bushels, and of Indian corn 40 or 50 bushels per acre. The ground was very light and easy to work, and Mr. Cummins estimated the actual expenses incurred per acre in this improving course, as follows:

<table>
<thead>
<tr>
<th>Description</th>
<th>Expenses per Acre</th>
</tr>
</thead>
<tbody>
<tr>
<td>First ploughing</td>
<td>$5 50</td>
</tr>
<tr>
<td>70 bushels lime, slaked, at 12 cts.</td>

<td>$13 73</td>
</tr>
</tbody>
</table>

Thus the whole expenses incurred preparatory to the wheat and clover crops, amounted to $13-73; and as the wheat raised was about 8 bushels, and sold for $1-50, and the clover mown about 1 ton per acre, worth about $ or 10 dollars the ton, the expenses were abundantly repaid by the first crop, and the land left in good heart for future profitable tillage.

When farms are situated near towns, animal manures can generally be obtained at fair prices, and hence the usual productiveness exhibited by lots and fields in the proximity of towns. But with large farms situated at too great distances from such places to admit of the transportation of stable manure or street dirt at fair prices, the farmers are left to the fertilizing substances at hand, or to the purchase of manufactured manure that will bear the cost of transportation, such as lime, ashes, soot, plaster, crushed bones, poudrette prepared from night soil, &c., the salts of nitre, soda, ammonia, etc. Those who live near enough to marl-beds to admit of the hauling of such heavy substances at a fair cost, are indeed fortunate. Then there are the manures or composts prepared from peat or bog-wood, by the addition of ashes, the salts of potash, soda, &c., the merits of all of which can now be readily ascertained from results of actual experiments, reported in numerous recent publications, upon agricultural matters, and especially in that highly valuable little treatise by Dr. Dana, "The Muck Manual."

FARM YARD. The area or court in which the farm buildings are situated, and which generally adjoins the farm-house. It is the place where cattle are foddered, dung prepared, and several other necessary operations belonging to the farm performed.

FARM-YARD MANURE. Of all fertilizers the most universal and most valuable to the cultivator, and yet the most generally mismanaged, is farm-yard manure, which has been often well described as the farmer’s sheet anchor. From this fertilizer, man must have derived some benefits, even before he was compelled, by the increase of population, to cultivate and manure his land. It is the earliest mentioned of all manures; although, at first, the only notice we meet with of dung and dunghills, describes them as employed in Palestine for fuel; and, to this day, in the barren deserts of the East, that of the camel, after being dried in the sun, is the only combustible article the natives possess. (Ezek. iv. 12, 15; Niebuhr's Voyage, i. 121.) This manure is noticed by the earliest agricultural writers. M. P. Cato tells us, in his fourth chapter, to "study to have a large dunghill; keep your compost carefully; when you carry it out, scatter it and pulverize it; carry it out in the autumn. Lay dung round your corn or your olive trees in autumn." And in his 29th chapter, "Divide your manure; carry half of it to the field where you sow your provener: and if there are olive trees, put some dung to their roots." And in c. 37, he advises the use of pigeons’ dung for gardens, meadows, and corn land, as well as amurca, which is the dregs of oil; and recommends the farmer to preserve carefully the dung of all descriptions of animals. These directions were given 150 years B. C.; after a lapse of nearly 2000 years, the direction to the farmer must still be the same; little can be added to the advice of Cato, when he said, "Study to have a large dunghill." Virgin is still more
FARM-YARD MANURE.

particular; in his description of fertilizers, he mentions with common manure, ashes (Georg. L. i. v. 80). Pumice-stone and shells (L. ii. v. 346—350, and 350—358). Varro (c. 38, l. i.) mentions many kinds of animal manure, and is particularly minute in his enumeration of the dung of birds, and includes even that of blackbirds and thrushes kept in aviaries. Columella (L. ii. c. 5) advises the cultivator not to carry out to the field more dung than the labourers can cover with the soil the same day, as the exposure to the sun does it considerable injury; and he enumerates (L. ii. c. 15), as well-known fertilizers, night-soil the excrements of birds and sheep, urine (especially for apple-trees and vines), dregs of oil, the excrements of cattle, of the ass, the goat, of pigs; ashes, chopped stalks of the lupine leaves, of trees, brambles, &c., and mud from sewers or ditches.

Of the early inhabitants of Britain, Pliny tells us (b. xvii. c. 6, 7, 8), that they highly valued the use of marl for particular soils, but on other lands they never employed it. We are told that they grew corn, and lived in houses thatched with straw, which would necessarily require an attention to fertilizers. They had also, according to Strabo (Geography, p. 306), gardens, which could not have been cultivated, neither could their apple orchards have flourished, without manure. The Roman invasion taught the original inhabitants better modes of using fertilizing materials; but their Saxon successors, in all probability, knew less of agriculture than the natives. War and fighting was their profession; they held the husbandman in much contempt. The confusion attendant upon British, Saxon, and Danish inroads, still farther retarded, in England, the progress of agriculture, which never prospered in a poor disturbed country. The very laws made in those days for its encouragement shew to what a low ebb the art of cultivating the land was then reduced. Thus it was provided, that if any one had the use of a field, the landholder, or the owner of it, consented, to use it for one year; and if the quantity of manure conveyed was in considerable quantities, so as to render it necessary to employ a cart, he was then entitled to use the land for three years; and if any person, with the consent of the owner of the soil, folded his cattle on it for the space of a year, he was then entitled to cultivate it for four years for his own benefit. (Legas Wallia, p. 268.) All these laws were evidently for the purpose of encouraging the better manuring of the land; but the necessity of such an disruption betrays the poverty of the farmers of those days, and the insufficiency of their live-stock. In the middle ages little was done for agriculture. The monks, after the introduction of Christianity, were the most learned and skilful in the best modes of applying manures. They early excelled in their gardens. The population of England in those days, however, was too limited to require the cultivation of inferior soils. In 1570, Conrad Heresbach, a learned German, published his four books of husbandry, which were translated by Googe: he there mentions the several descriptions of manure employed in his days. His book is a strange mixture of good sense and superstition. He speaks of the dung of poultry and pigeons with much approbation; but reprobrates the use of that of geese and ducks. Human fishes, he says, when mixed with rubbish, is good; but, by itself, is too hot. Urine he commends highly for apple trees and vines. Of the dung of animals, he mentions that of the ass as first in order for fertilizing effects; then that of sheep, goats, oxen, horses; lastly, swine, “very hurtful to corne, but used in some places for gardens.”

Green manure was not used in his days. “Where they have no manure, they used to mend their ground with straw, fern, and the stalks of lupines, and the branches, laid together in some ditch. Hereunto you may cast ashes, the fifth of sinks and privies, &c.” And again he says, “The weeds growing about willow trees and fern, &c., you may gather and lay under your sheep.” He speaks of the practice of placing turfs and heath cloths in heaps, with dung; much in the same way as Lord Meadowbank has advised with peat. He also advises the placing of the same turf-parings in sheep-folds. “This is also to be noted,” says our author, “that the dung that hath lyen a yeare is best for corne, for it both is of sufficient strength and breedeth less weedes; but, upon meadowe and pasture you must laye the newest, because it brings most grasse, in February, the moone increasing, for that is the best time to cause increase of grasse.” When, however, the manure is applied for corn lands, “looke that the winde be wearyly, as the moone in the wane.”

The manure commonly furnished by the farm-yard is compounded of a mixture of animal and vegetable substances of the purely-fying straw of various descriptions of grain, mixed with the excrements and urine of cattle, horses, and swine. The mixture forms no new substance, neither does the putrefaction which ensues add to the bulk of the dung; on the contrary, it excises a proportion, or less, than the original weight. Neither is the manure produced equal to the amount of food the stock consume. “If,” says Dr. Sprengel “we weigh the dry food given the cattle to eat, and also dry and weigh the resulting excrements, we shall find the weight of the latter considerably less than that of the former. Block, who has lately made a great number of experiments on this circumstance, found that 100 lbs. of rye-straw yielded only 43 lbs. of dried excrement (liquid and solid), while 100 lbs. of hay gave 44 lbs. Food which contains many watery parts is furnished, as may be naturally supposed, a still smaller proportion. Thus, for instance, 100 lbs. of potatoes gave only 14 lbs.; 100 lbs. of mangel-wurzel, 6 lbs.; and 100 lbs. of green clover, 9½ lbs. of excrement.” (Transl. by Mr. Hudson, Jour. Roy. Agr. Soc. vol. vi. p. 460.)

It will assist us very materially in our examinations of various modes of preparing and applying manure, if we first examine its chemical composition; and for that purpose I will give the analysis of straw and the feces and urine of animals.

1000 parts of dry wheat straw being burned, 455
FARM-YARD MANURE.

yielded M. Saussure 48 parts of ashes; the same quantity of the dry straw of barley yielded 42 parts of ashes. The portion dissipated by the fire would be principally carbon (charcoal), carburetted hydrogen gas, and water: 100 parts of these ashes are composed of—

The feces of cattle fed principally on turnips have been analyzed by M. Einholt. 100 parts evaporated to dryness yielded 28½ parts of solid matter; the 71½ parts lost in drying would consist principally of water and some ammoniacal salts. In half a pound, or 3840 grains, he found 45 grains of sand; and by diffusing it through water he obtained about 60 grains of a yellow fibrous matter, resembling that of plants, mixed with a very considerable quantity of slimy matter. By evaporating the feces to dryness and then burning them, he obtained an ash which contained, besides the sand, the following substances:—

The ingredients of which the urine and feces of cattle are composed, will, of course, differ slightly in different animals of the same kind, and according to the different food upon which they are fed; but this difference will not in any case be found very material.

The excreta of the sheep have been examined by Block; according to him, every 100 lbs. of rye-straw given as fodder to sheep yield 40 lbs. of excrements (fluid and solid); from 100 lbs. of hay, 42 lbs.; from 100 lbs. of potatoes, 13 lbs.; from 100 lbs. of green clover, 52 lbs.; and from 100 lbs. of oats, 48 lbs. of dry excrement. The solid excrements of sheep fed on hay were examined by Zierl: 1000 parts by weight, being burnt, yielded 96 parts of ashes, which were found to consist of—

(Jour. Roy. Agr. Soc. vol. i. p. 489.)
of the soluble salts are usually washed away by the rain, or are suffered to drain away into ditches, whilst a considerable quantity of the salts of ammonia and some of the carbon are commonly lost by being either over-heated, or by being allowed to remain too long in a putrefying state. Farm-yard manure has a very considerable attraction for the moisture of the atmosphere: some experiments to ascertain its extent are given under the head Manure. There have been many arguments and much difference of opinion among cultivators, with regard to the advantages of employing dung in a fresh or in a putrid state; and, as is too often the case, both parties have run into extremes, the one side contending for the propriety of employing it quite fresh from the farm-yard, the other contending that it cannot well be too rotten. The mode employed by Lord Leicester is the medium between these equally erroneous extremes. He has found that the fresh dung certainly made the dung go much farther; but then a multitude of the seeds of various weeds were carried on to the land along with the manure. He has, therefore, since used his compost when only in a half putrefied state (called short dung by farmers); and hence the seeds are destroyed by the effects of the putrefaction, and the dung still extends much farther than if suffered to remain until quite putrefied. Putrefaction cannot go on without the presence of moisture. Where water is entirely absent there can be no putrefaction; and hence many farmers have adopted the practice of pumping the drainage of their farm-yards over their dung-heaps; others invariably place them in low damp situations. This liquid portion cannot be too highly valued by the cultivator. The soil where a dunghill has lain in a field is always distinguished by a rank luxuriance in the succeeding crop, even if the earth beneath, to the depth of six inches, is removed and spread with the dunghill. The controversy, too, which once so keenly existed, as to the state of fermentation in which dung should be used on the land, has now pretty well subsided. There is no doubt but that it cannot be applied more advantageously than in as fresh a state as possible, consistent with the attainment of a tolerably clean husbandry, and the destruction of the seeds of weeds, grubs, &c., which are always more or less present in farm-yard dung. These are the only evils to be apprehended from the adoption of this universal employment of the manure in the freshest state; for otherwise the loss of its most valuable constituents commences as soon as ever fermentation begins. This was long since demonstrated by Davy, whose experiments I have often seen repeated and varied. He says, "I filled a large retort, capable of containing three pints of water, with some hot fermenting manure, consisting principally of the litter and dung of cattle; I adapted a small receiver to the retort, and connected the whole with a mercurial pneumatic apparatus, so as to collect the condensible and elastic fluids which might arise from the dung. The receiver soon became lined with dew, and drops began, in a few hours, to trickle down the sides of it. Elastic fluid likewise was generated; in three days thirty-five cubical inches had been formed, which, when analyzed, were found to contain twenty-one cubical inches of carbo-acid; the remainder was hydrocarbonate, mixed with some azote, probably no more than existed in the common air in the receiver. The fluid matter collected in the receiver at the same time amounted to nearly half an ounce. It had a saline taste, and a disagreeable smell, and contained some acetate and carbonate of ammonia. Finding such products given off from fermenting litter, I introduced the beak of another retort, filled with similar dung very hot at the time, in the soil amongst the roots of some grass in the border of a garden; in less than a week a very distinct effect was produced on the grass: upon the spot exposed to the influence of the matter disengaged in fermentation it grew with much more luxuriance than the grass in any other part of the garden." (Lectures, p. 294.) Nothing, indeed, appears at first sight so simple as the manufacture and collection of farm-yard dung; and yet there are endless sources of error into which the cultivator is sure to fall, if he is not ever vigilant in their management. The late Mr. Francis Blakie, in his valuable tract upon the management of farm-yard manure, dwells upon several of these; he particularly condemns the practice of keeping the dung arising from different departments, and applying them to the land without intermixture. It is customary," he adds, "to keep the fattening neat cattle in yards by themselves; and the manure thus produced is of good quality, because the excrement of such cattle is richer than that of lean ones. Fattening cattle are fed with oil-cake, corn, Swedish turnips, or some other rich food; and the refuse and waste of such food thrown about the yard increases the value of the manure; it also attracts the pigs to the yard. These rout the straw and dung about, in search of grains of corn, bits of Swedish turnips, and other food: by which means the manure in the yard becomes more intimately mixed, and is proportionally increased in value. The feeding-troughs and cribs in the yard should, for obvious reasons, be shifted frequently." "The horse dung," continues Blakie, "is usually thrown out at the stable doors, and there accumulates in large heaps. It is sometimes spread several times about the stable by the attendants, and is not at all, unless where necessary for the convenience of ingress and egress, or perhaps to allow the water to drain away from the stable door. Horse dung, lying in such heaps, very soon ferments, and heats to an excess; the centre of the heap is charred or burned to a dry white substance, provincially termed for-fanged. Dung in this state loses from 50 to 75 per cent. of its value. The diligent and attentive farmer will guard against such profligate waste of property, by never allowing the dung to accumulate in any considerable quantity at the stable doors. The dung from the feeding-hogs-sties should also be carted and spread about the stable cattle-yard, in the same manner.
as the horse dung. (Blakie on Farm-yard Dung, p. 6.) There is no doubt of the superior fertilizing effects of horse-dung. In an experiment with beans, in which six acres were manured with horse-dung, and nine with that from a cow-yard, the six yielded more beans than the nine. (Agr. Rep. of Essex, vol. ii. p. 280.) The same observation was made in Lincolnshire. (Sinclair's Agr., p. 214.) The heat produced by the fermentation of the dung of different animals has been made the subject of repeated experiment. When the temperature of the air was 40°, that of

| Common farm-yard dung was | A mixture of lime, dung, and earth | - | - | - | -
| Street wine and fowls' dung | - | 55° | - | - | -

(Blakie on Farm-yard Dung, p. 6.)

There is no doubt of the superior fertilizing effects of horse-dung. In an experiment with beans, in which six acres were manured with horse-dung, and nine with that from a cow-yard, the six yielded more beans than the nine. (Agr. Rep. of Essex, vol. ii. p. 280.)

The cultivator will readily allow the advantages of the plan thus recommended by Mr. Blakie; and the student must see from the following experiments, that the dung of different animals vary very much in their fertilizing powers.

The subjoined table contains the results of the experiments made with three different manures on the growth of potatoes, by Mr. Oliver, of Mid-Lothian; the cow and horse-dung were recently made; the potatoes were of the description called Pinkeyes, and forty loads of about eighteen cwt. per acre were employed of each manure. (Ency. Metrop. vol. vi. p. 61.)

Malcolm (see Brit. Husb. vol. i. p. 260) has given an estimate of the number of cubic yards or tons of farm-yard compost necessary for various soils per acre, which is as follows:

Some experiments of Mr. Wright, made upon plots of ground of equal size, indicate the number of stems of barley produced by various fertilizers; each plot was dabbled with 60 corns of barley. (Agr. Mag. vol. i. p. 328.)

With regard to the form of dung-yards, there is some little difference of opinion. "Some theorists," says Blakie, "recommend the yards to be made so concave, as almost to amount to a well-shape, giving, as a reason in support of their opinion, that the virtues of dung can only be preserved by being saturated in urine, or some other moisture. Others, again, insist that dung-yards should be formed convex, and assign as their reason, that farm-yard dung should be kept dry. Practical experience points out that a medium between those two extremes is the best; and a yard a little hollowed is the most common shape."

I will here introduce the description recommended by Mr. Blakie, of the best mode of forming dung-heaps or pies in turnip-fields, so as to prevent, as much as possible, the waste of gaseous matters, during the fermentation of the manure. "When," said this intelligent agriculturist, "it is found necessary to empty the dung-yards early in the season, I recommend that preparation should be made, in the usual way, for the reception of the dung-heaps in the intended turnip-fields, by collecting large heaps of clay marl, or such other materials. The bottom of the dung-heaps should be, however, be laid above six or eight inches thick of the earthy material, and a good quantity of it should be placed in rows on each side of the bottoms marked out; the dung should then be drawn out of the yards, and placed upon the bottoms, but not in the usual way of throwing it up loosely, to cause fermentation; on the contrary, by drawing the carts with their loads upon the heaps, for the purpose of compressing the dung, and thereby retarding fermentation. One or two men should remain constantly at the heaps, while the teams are at work, on purpose to spread and level the dung regularly, so as to render the ascent easy for the succeeding teams, as they come with their loads. If the dung has not been previously mixed in the yards; it should be in drawing to the heaps, by taking up a few loads from one yard, and then a few from another, alternately; and even from the same yard, the loads of dung should be taken from different parts alternately; for the dung is not of equal quality, nor made with the same regularity, in all parts of the yard."

"The coal-ashes, road-scrapings, and all other collections of manure about the farm-house, should also be carried to these dung-heaps; and when the heaps are raised as high as convenient for the horses to draw up, several loads should be shot up at the ends of the heaps, for the purpose of making them up to the square of the centre. The whole heaps should then be completely covered with the marl and clay, or soil previously collected in rows by the sides of the heaps, so as effectually to enclose the dung-heaps in crusts, and they are thenceforth denominated pies. In these, the dung will be preserved in a very perfect state, with little or no fermentation, and without loss by exhalation or evaporation. The pies, within ten days or a fortnight of the time the compost is wanted for the turnip ground, should be turned carefully over, and the crust, top, bottom, and sides intimately mixed up with the dung. When the turning is completed, with the natu-
FARM-YARD MANURE.

rul soil around the heaps, again coat the heaps all over; the pies will then undergo a gentle fermentation; the earth, intermixed with and covering the dung, will absorb the juices and gaseous matters produced, and the compost come out in a fine state of preparation for using on the turnip lands. When the dung is taken out of the yards late in the spring, or only a short time before it is required for the turnip ground, the preparation should be somewhat different, because of the compost heaps having less time to incorporate. Thus the dung should not be carted upon the heaps to compress them, and prevent fermentation, as in winter. On the contrary, the dung should be thrown up lightly with the fork upon the bottoms, and the side-heaps of earth mixed intimately along with the dung. Turf turned up for a year preceding on wastes by the sides of roads makes excellent pie-meal."

The temperature of the dung-heap is a pretty sure criterion of the state of its fermentation. If a thermometer, plunged into it, does not rise above 100°, there is little danger of too much gaseous matter being lost. If the temperature is higher, means should be taken to check the fermentation; and the same overheating may be regarded as going on, if, when a piece of paper moistened with muriatic acid is held over a dunghill, dense fumes appear, for then ammonia is disengaging. (Davis, p. 307.) With skilful management, and under ordinary circumstances, one ton of dry straw is found to produce three tons of manure; so that, as the common weight of straw per acre is about one ton and a half, the straw grown upon that extent of land should yield about four tons and a half of compost. The quantity of manure produced by stock necessarily varies with the quantity and quality of the food upon which the animals are fed. In an experiment made at the Cavalry Depot, at Maidstone, a horse consumed in a week—

</table>

she produced, under the same circumstances, 73 lbs. of solid manure. (British Husbandry, vol. i. p. 355.) Taking, therefore, the average produce to be equal to 60 lbs. per day, it follows that a cow will make about 9 tons of solid dung in the course of the year.

The quality of farm-yard compost naturally varies with the food of the animals by which it is made: that from the cattle of the straw-yard is decidedly the poorest; that from those fed on oil-cake, corn, or Swedes, the richest. Of stable-dung, that from corn-fed horses is most powerful—from those subsisting on straw and hay, the poorest; the difference between the fertilizing effects of the richest and the inferior farm-yard dung is much greater than is commonly believed—in many instances the disparity exceeds one-half; thus, that produced by cattle fed upon oil-cake is fully equal in value to double the quantity fed upon turnips. My friend, Mr. Hewitt Davis, of Spring Park, near Croydon, an excellent scientific practical farmer, had occasion to notice this in an experiment which commenced in 1834. In that year, on half of a field of turnips fed off with sheep, he gave them oil-cake; on the other half they fed only on the turnips. The succeeding crops were all distinguished by their superiority on the half of the field where the sheep had oil-cake; and in 1838, when the field had again a crop of turnips, the field for which four years previously the sheep were fed with oil-cake, had by far a better crop of turnips than that which had been manured in common with the rest of the field and fed off in the ordinary manner. And as the food consumed so materially influences the quality of the manure, it follows, as a natural consequence, that that made in summer by the clover, grass, and tare-fed stock is much superior to that produced during the winter months by the store-fed cattle of the straw-yard, which is usually still further impoverished by the rains and snows. Hence, too, the superior richness of the manure of fatting swine to those of pigs in a lean state, and the far superior strength of night soil to any manure produced from merely vegetable food. Chemical examinations are hardly necessary to prove these facts. Every farmer who has had stall-fed cattle will testify to their truth—every cultivator will readily acknowledge the superiority of "town-made," that produced stable-dunging, to that from horses fed only on hay and straw, and that night-soil is far superior in "strength" to either. The relative quantities employed by the cultivator betray the same fact; for on the soils where he applies 20 loads of good farm-yard compost per acre, he spreads not half that quantity of night-soil. Mr. Dixon, whose observations I have quoted at some length in this paper, deems "six tons of night-soil in compost with peat amply sufficient for an acre." Mr. H. Davis is of the same opinion. It is not, as the farmer is well aware, the mere straw on the farm-yard manure which influences its fertilizing quality, but the excrements with which that straw is mixed. Thus other substances, when thoroughly saturated with the stercoreous matters of cattle, are found to be just as fertilizing as straw: sawdust, peat, tanners' bark, or turf, are as serviceable in this respect as the best straw. Arthur Young found this to be the case when turf was employed mixed with
urine. (Annals of Agric. vol. ix. p. 652.—Ibid. vol. iii. p. 67—69.) Lord Meadowbank, Mr. Dixon, and others have successfully employed peat in a similar way (English Agric. Soc. Journ. vol. i. p. 198), and the latter agriculturist often makes his excellent compost heaps of merely peat and urine. The liquid or soluble portion of farm-yard manure constitutes, in fact, its richest portion. Of the powerful effect produced by the urine of cattle, and other liquid fertilizers, I shall have hereafter occasion to speak, when treating on liquid manure.

It is usual for the farmer, although not so common a practice as is desirable, to increase the bulk, if not the quality, of his dung-heaps, by adding to them various other substances; thus, as to enlarging them, by adding to that of the farm-yard, peat-moss, the late Lord Meadowbank made many experiments with success; and his directions are of a very simple and easily followed description. "Let the peat-moss," he says, "be thrown out of the pit for some weeks or months, in order to lose its redundant moisture. By this means it is rendered the lighter to carry, and less compact and heavy when made up with fresh dung for fermentation; and, accordingly, less dung is required in the preparation than if the peat-moss is made with peat taken recently from the pit; the peat taken from near the surface or at a considerable depth answers equally well. Take the peat-moss to a dry spot convenient for constructing a dunghill, to serve the field to be manured; lay the cart-loads of it in two rows, and of the dung in a row between them. The dung thus lies nearly on an area of the future compost dunghill, and the rows of peat should be about six inches deep and fifteen feet wide, if the ground admits of it; then throw forward and lay on about ten inches of dung above the bottom of peat, then add from the side rows about six inches of peat, then four inches of dung, and then six more of peat; then another thin layer of dung, and then cover it over with peat at the end where it was begun, and at the two sides. The compost should not be raised above four feet or four feet and a half high, otherwise it is apt to press too heavily on the under parts, and check the fermentation; when a beginning is thus made, the workmen will proceed working backwards, and adding to the column of compost, as they are furnished with the three rows of materials directed to be laid down for them. They must take care not to tread on the compost, or render it too compact; and, of consequence, in proportion as the peat is wet, it should be made up in lumps, and not much broken. In mild weather, 7 cart-loads of common farm dung, tolerably fresh made, is sufficient for 21 cart-loads of peat-moss; but, in cold weather, a larger proportion of dung is desirable. To every 28 cart-loads of the compost when made up, it is of use to throw on above it a cart-load of ashes, either made from coal, peat, or wood; or, if these cannot be had, half the quantity of slaked lime may be used, the more finely powdered the better; but these additions are nowise essential to the general success of the compost. The dung to be used should either have been recently made or kept fresh by compression, as by the treading of cattle or swine, or by carts passing over it; and if there is little or no litter in it, a smaller quantity will serve, provided any spongy vegetable matter is added at making up the compost, as fresh weeds, the rubbish of a stack-yard, potato-shaves, savings of timber, &c.; and as some sorts of dung, even when fresh, are much more advanced in decomposition than others, due attention to this; for much less proportion of such dung will advance will serve for the compost, provided care is taken to keep the mass sufficiently open, either by a mixture of the above-mentioned substances, or, if these are wanting, by adding the peat piecemeal; that is, first making it up in the usual proportion of three to one of dung, and then adding, after a time, an equal quantity more or less of moss. The dung of this quality of greatest quantity is shamble dung, with which, under the above precautions, six times the quantity of peat, or more, may be prepared. The same holds as to pigeons' dung and other fowl dung, and, to a certain extent, also, as to that which is collected from towns, and made by animals that feed on grains, refuse of distilleries, &c.

"The compost, after it is made up, gets into a general heat sooner or later, according to the weather and the condition of the dung: in summer, in ten days or sooner; in winter, not perhaps for many weeks, if the cold is severe. It is always, however, has been found to come on at last; and in summer it sometimes rises so high as to be mischievous, by consuming the materials (Fire-Fanging). In that season a stick should be kept in it in different parts, to pull out and feel now and then; for, if it approaches to blood heat, it should either be watered or turned over, and, on such an occasion, advantage may be taken to mix it with a little fresh moss. The heat subsides after a time, and with great variety, according to the weather, the dung, and the perfection of the making up of the compost, which then should be allowed to remain untouched till within three weeks of using, when it should be turned over upside down, and outside in, and all lumps broken; then it comes into a second heat, but soon cools, and should be taken out for use. In this state the whole, except bits of the old decayed wood, appears a black, free mass, and spreads like garden manure. Use the weight for weight as farm-yard dung, and it will be found in a course of cropping fully equal to stand the comparison." After a long-continued observation and successful use of peat, Mr. H. Davis is of opinion that peat, in common with most organic manures, has a strong tendency to rise to the surface of all cultivated soils, thus following a rule directly opposite to those of earthy fertilizers, which certainly descend into the land. (Young's Annals, vol. xi. p. 547.)

Compost, if made up before January, has hitherto been in good order for the spring
FARM-YARD MANURE.

cropped; but this may not happen in a long frost. In summer, it is ready in eight or ten weeks; and, if there is an anxiety to have it sooner prepared, the addition of ashes, or of a little lime rubbish of old buildings, or of lime slack-

shot, will speedily modify, in making up, will quicken the process consider-

ably. “Pest prepared with lime alone has not been found to answer as good manure; in one instance, viz. on a bit of fallow sown with wheat, it was manifestly pernicious.” (Edinburgh Enqrc., vol. i. p. 279.) The opinion of Lord Meadowbank in favour of the use of peat or sawdust as a mixture with farm-yard compost, has been recently confirmed by Mr. Dixon, of Hathershaw, in Lancashire, who, in his Prize Essay, thus describes the result of his long experience (Journ. of the English Agric. Society, vol. i. p. 133):—

“My farm is a strong, retentive soil, on a substratum of ferruginous clay. My object was to improve its texture at the least cost. For this purpose we carted great quantities of fine sawdust and peat-earth, or bog; but we had so far to go for the latter, that two horses would fetch little more than three tons in one day; one horse would fetch three cart-loads of saw-

dust in the same time. Having brought great quantities of both peat and sawdust into my farm-yard, I laid out, for the bottom of a com-
post heap, a space of considerable dimensions, and about three feet in depth; three-fourths of this bottom was peat, the rest sawdust; on this we conveyed, daily, the dung from the cattle-

sheds; the urine, also, is conducted through channels to wells for its reception (one on each side of the compost heap); common water is entirely prevented from mixing with it. Every second day the urine so collected is thrown over the whole mass with a scoop, and at the same time we regulate the accumulated dung. This bottom, four or five inches, or a foot thick, of peat and saw-

dust (and frequently peat without sawdust) is wheeled on the accumulated heap. These matters are continuously added to each other during winter; and, in addition, once in every week, never less than 25 cwt., more frequently 50 cwt., of night-soil and urine: the latter are always laid next above the peat or bog earth, as we think it accelerates their decomposition. It is, perhaps, proper here to state, that the peat is dug and exposed to the alternations of the weather for several months before it is brought to the heap for admixture: by this it loses much of its moisture. Some years’ ex-

perience has convinced me of the propriety of using recently dug peat: used in the man-

ner I recommend, it is superior and more con-

venient on every account; very much lighter to cart to the farm-yard, or any other situation where it is wanted; and so convinced am I of its utility in composes for every description of soil, except that of its own character, that wherever it can be had down on a farm at less than 4 shillings per ton, I should recommend every agriculturist and horticulturist that can com-

mand it, even at the cost here stated, to give it a fair trial. So attractive and retentive of mois-

ture is peat, that, if liberally applied to an arid, sandy soil, that soil does not burn in a dry

season, and it so much improves the texture and increases the produce of an obdurate clay soil, if in other respects rightly cultivated, that actual experience alone can fairly determine its value.

“For the conveyance of night-soil and urine, we have the largest and strongest casks, such as oils are imported in; the top of which is provided with a funnel to put the matters through, and the casks are fixed on wheels like those of a common dung-cart. For the conven-

cience of emptying this carriage, the compost heaps are always lower at one end; the high-

est is where we discharge the contents, in order that they may, in some degree, spread them-

selves over the whole accumulation. The sit-

uation on which the wheels of these carriages stand while being discharged, is raised consi-

derably; this we find convenient, as the com-
post heap may be sloped six or seven feet high; low compost heaps, in my opinion, should be avoided. The plan here recommended I have carried on for some time. I find no difficulty in manuring my farm over once in two years; by this repetition I keep up the fertility of my land, and it never requires more than a moderate application of manure.

“I am fully aware that there are many loca-

lities where neither peat nor night-soil can be readily obtained; but it is worth a farmer’s while to go even more than 20 miles for the latter substance. Provided he can have it with-

out deterioration: the original cost is often trifling. On a farm where turnips or mangel are cultivated to some extent, the system here recommend-

ed will be almost incalculably advan-

tageous. A single horse is sufficient for one carriage: nine hold upwards of a ton each; six tons of this manure in compost with peat, or, if that is not convenient, any other materials, such as ditch scourgings, or high-head-

ands which have been properly prepared and laid dry in a heap for some time, would be am-

ply sufficient for an acre of turnips or mangel. This manure is by far the most invigorating of any I have ever yet tried; bones in any state will bear no comparison to it for any crop; but it must be remembered that I write on the supposition that it has not been reduced in strength before it is brought.

“Convenience frequently suggests that compost heaps should be raised on different parts of a farm; but, unless in particular instances, it is well to have them in the yard. In the farm-yard, all the urine from the cattle-stalls may be employed with the greatest economy; and, be it remarked, that the urine from ani-

mals, in given weights, is more powerful than their solid excrements. How important, then, must it not be to the farmer to make the most extensive and the most careful use of this liquid? It is sometimes carted on the land; but that practice will not bear a comparison with making it into composes in the manner here recommended. Great waste is often made in putrescent manures after they are carted on the land; instead of being rendered or incorporated with the soil, we not un-

frequently see them exposed for days together in the hot rays of a scorching sun, or to the injurious influences of a dry wind. I have before
FARM-YARD MANURE.

stated that compost heaps should, on many considerations, be raised in the farm-yard; still, circumstances are frequently such that it is more proper to make them at some distance in the field. If a headland becomes too high by frequent ploughings or working of the land, in that case it should be ploughed at the time when clover or mixed grass-seeds are sown with a white crop; for instance, barley or oats, and clover for the year following; a headland might then be ploughed, and a number of cart-loads of some manure heaped from one end to the other. Immediately after this it should be trenched with the spade (or what is sometimes called digging), and raised high, in order that an action may take place between the soil and the manure; by this means the mass would soon be in a condition for turning over, and any ditch scourgings, or other matters which had not in the first instance been used, might now be added to the mixture. The heap should then be allowed to remain closed for a few weeks, then turned over again; at this turning, in all probability, the mass would be much reduced; and if so, raise the ridge of compost well on both sides but, instead of its top being pointed, make a trench or cavity on the top from one end of the heap to the other. This cavity should be made tolerably retentive of moisture, which may be effected by treading with the feet; carriages of night-soil, or urine from the cattle-stalls, may then be emptied into the trench, and the bulk of the heap would determine how many were required. This being done, a little earth should be thrown into the trench, and the heap allowed to remain in that state until the middle or latter end of autumn; it will then be ready for another turning; but at this time care must be taken to have the heap well made up at the sides, and pointed at the top; in this situation rain will be thrown off, and the compost preserved dry until winter presents some favourable opportunity for laying it on the young clover, wheat, or any other crop which may require it.

"In the year 1826," adds Mr. Dixon, "my attention was first directed to raising compost heaps from urine. This I now do frequently, without the help of any dung from the cattle-stalls. The same occasion called my mind to another matter, well worthy every farmer's attention. I allude to the great superiority of the manure raised in summer soiling, to that produced in the stalls during winter."

"The strength and consequent value of all cattle-dung," says Mr. Burke, in a note upon this paper, "will of course depend upon the nature of their food; if soiled, during the summer, upon clovers, tares, sainfoin, &c., there can be no doubt that the manure will have a proportionately greater effect upon the land, than if the beasts be kept in the straw-yard; and if stall-fed, either in winter or in summer, for the purpose of fatting, it will be still better. Thus, it was found, on comparing the effects of dung voided by animals fed chiefly on oil-cake with that of store-stock, 12 loads of the former exceeded in superiority of product 24 of the latter." (See The Complete Grazier, 6th edit. p. 163.)

I verily believe the difference is 60 per cent., unless stock are fed, in a great measure, during winter, with artificial food. In an arrangement for making compost heaps from urine, I would recommend a receptacle to be made at the back of the cattle-stalls, just outside the building: this should hold about 20 cart-loads of mould, or any other matters to be employed; if its situation were a little lower than the cattle-sheds, all the urine would pass into it, and remain there until the mass is completely saturated, which will be sufficient; when the earthy matters are covered over, the compost may then be thrown out, and the proceeding again renewed. In order to show part of the benefits of this practice, I beg here to observe, that the most foul or weedy mould may be used; the action of the urine, if not reduced by water, is so powerful, that wire-worms, the black slug, many other destroying insects, and all vegetables, weeds, &c., when in contact with the urine for a time, are killed. The situation for raising this compost should be protected from the weather by a covering, similar to a cart-shed; indeed, the deteriorating influence of rains, sun, and arid winds, on all putrescent manures or compost, are so serious, that, in my humble judgment, it would be worth while to have places under cover where these are usually laid down. The ordinary method of conveying manures on land, admits of much improvement.

On the black hungry gravels of Spring Park, near Croydon in Surrey, peat has been long and skilfully applied, with the best success, by Mr. Hewitt Davis. The peat on his farm is found resting in considerable situations strata; he uses it both mixed with his farm-yard compost, and also with lime; in the first case, he has the peat previously dried; in the latter, the operation of the lime, absorbing the moisture of the peat as it slakes, renders drying unnecessary; he finds the lime and peat an admirable top-dressing for young clover. To the compost of the farm-yard he adds about an equal bulk of peat: he also burns a considerable quantity of peat, and with the ashes top-dresses his turnips with decided advantage; if not, he reduces the growth of the crop, but he thinks that the smell of the ashes is very noxious to the turnip fly. There is no doubt but that peat, when saturated with urine, and in a state of gradual decomposition, is nourishing to plants. Mr. Davis has noticed that when the land is manured with the peat and farm-yard compost, the roots of the turnips and tares will encircle the lumps of peat, just as is the case when crushed bones are employed. I am not aware of any farm of similar extent (500 acres), where peat has been more skilfully and successfully applied than at Spring Park, under the management of this able agriculturist. Peat, which has thus been so successfully employed as a manure in compost, is composed principally of the inert, long accumulating vegetable remains of either wood, moss, or heath; it abounds also with earthy and saline matters; those of Berkshire and Wiltshire contain from one-fourth to one-third of their weight of gypsum; their earthy matters are always analogous to the stratum of earth on which it repose; where that is chalk, the peat abounds with
calcareous earth and gypsum, and but little alumina or silica. “Different specimens of peat, that I have burnt,” says Davy, “from the granitic and schistose soils of different parts of these islands, have always given ashes principally silicious and aluminous; and a specimen of peat from the county of Antrim gave ashes which afforded very nearly the same constituents as the great basaltic stratum of the county.” (Chemistry, p. 192.) In those instances, where the farmer finds such excellent results from dressing young clover with a mixture of peat and compost, as noticed by Mr. Dixon, with the Lancashire peat, it may be reasonably concluded to contain gypsum; (Journ. Eng. Agr. Soc. vol. i. p. 138); and, if it requires the addition of a portion of lime, before it is found to promote very decidedly the growth of clover, it then is very likely to be saturated with sulphate of iron.

The too general neglect of peat as a mixture with farm-yard dung is not owing to its being a very modern discovery, for it was publicly recommended in England near half a century since. “In Sweden, as in other countries,” says the Baron de Schulz, when writing to Sir John Sinclair in 1796, “farmers have endeavoured to increase the quantity of manure by mixtures of all kinds of vegetables and soils, and by collecting urine in cow-houses well adapted for that purpose; they likewise, in some parts of the country, lay below their cattle soil from the shores of the lakes, leaves, moss, sawdust, chopped elder, and pitch fir, brushwood, reeds, and straw. They often now place their dunghills on a slope instead of the former hollow, and by means of pumps, water them with urine and dung-water. Many farmers, however, still prefer the fresh dung to that which is fermented, and which they suppose has lost in the process a great part of its vegetative power.” (Com. Board of Agr. b. i. p. 326.)

On the sea-shore, it is usual for the farmers to mix sea-weed with their dung; in Essex they mix it with chalk; in Suffolk, with a peculiar red shelly sand or marl; and in the west of England, with the calcareous sand of the sea-shore; a practice which is thus described by Edward Bennet:

“The quantity of sand which a barrow usually contains is about 90 horse teams of 2 1/2 cwt. each; the price varies according to the distance it is carried up the rivers Otter and Tamar, from 18s. to 25s., and 3s. drinking money, or three gallons of cider. It is dragged for in Plymouth sound in three to six fathom water. In summer, the barrows frequently run on the sand bank in Whitsand Bay at two hours before low water; when the tide leaves them, they load, waiting for the flood to bring them off. For arable land, the sand is thought to be best mixed with old earth, or manure collected in roads; but for pasture it is best mixed with stable muck; the proportion is two teams of muck to one of sand; a barrow load thus mixed is thought to be good manure for an acre.” (Annals of Agr. vol. xii. p. 35.)

Farm-yard dung is usually employed in all experiments upon mixtures, as the basis upon which comparative results are most usually obtained; and it is not often that any substance can be found to exceed it in fertilizing effects. It was compared with salt, lime, and oil-cake, by Mr. George Sinclair, most of whose elaborate experiments are given under the head SALT. In my own experiments with potatoes in a light gravelly soil, I found that when the soil simply produced 120 bushels per acre, that manured with 30 tons of stable dung it yielded 219 bushels; and with 20 bushels of salt only 192½ bushels. (My Essay on Soil, p. 84.) In those of my brother, Mr. George Johnson, where 20 tons per acre of stable dung produced 23 tons of carrots, 20 bushels of salt applied to a similar space produced 18 tons (Ibid. p. 146); and, with the same proportions, when the salted soil produced 43½ tons of red beet-root, the spit manure yielded 61 tons. (Ibid. p. 149.) In those of the Rev. E. Cartwright upon potatoes, when the soil simply produced 157 bushels per acre, the same quantity of land when dressed with

Some valuable experiments on farm-yard dung, compared in various proportions with other manures, applied to potatoes and oats, were made by Arthur Young, of which the following was the result:

“In the last week in March, 1787,” he says, “the white champion potato was planted in beds, each containing a square perch of a good sandy loam, on a wet clay marl bottom, the sets being planted one foot apart.

“At the same time, and on the same ground, 12 square perches were planted with the same potatoes, and manured as described in the following table, which also gives their respective products.
“The great product,” adds Young, “which attends the addition of urine to dung, affords a very important lesson; which is, to manage dunghills in such a manner as to save, if possible, every drop; this is a point too much neglected, and, indeed, by most common farmers very little attended to.” (Annals of Agr. vol. ix. p. 652.)

A rood of a poor blue pebbly gravel, which yielded turnips in 1770, in June, 1771, was marked in spaces for manures, each of two square perches, by Arthur Young, and sown with oats.

“...and, indeed, by most common farmers very little attended to.” (Annals of Agr. vol. ix. p. 652.)

A cubic yard of garden mould - cwt. qr. lb. - water - 15 0 7
- compost of dung, with weeds and lime, which had been once turned over in 9 mos. 14 0 5
- new dung - 9 3 18
- leaves and sea-weed - 9 0 7

There have been many excellent suggestions for the improvement of farm-yard manure. The late Mr. Blakie published an excellent essay, of which I have largely availed myself. Mr. Kirk, of Preston Mains (Quart. Journ. of Agr. vol. viii. p. 483), has suggested that the straw produced by different soils should be kept separate, and, when made into manure, applied to different soils. Mr. Pearson has very properly (Quart. Journ. of Agr. ix. p. 299), condemned the careless way in which farm-yard manure is often flooded with the rain water from buildings, &c. Mr. Baker is an advocate for using farm-yard manure in its freshest state. (Quart. Journ. of Agr. vol. vii. p. 584, and ix. p. 597.) Mr. W. Sim has reported several comparative experiments at Drummond, in Ross-shire, with barley. The soil a good deep loam on a gravelly subsoil; the previous crop, peas. (Journ. Royal Agr. Soc. vol. i. p. 419.)

A treatise recently published at Lowell, Massachusetts, by Dr. S. L. Dana, under the title of “Muck Manual,” contains much highly interesting matter relative to the preparation and qualities of farm-yard and other kinds of manures.

FARRIER (Fr. ferrier: Lat. ferrarius). A person who forges horses’ shoes. As the errors committed by ignorance in this art were the cause of many diseases in the feet of horses, it naturally followed that farriers were resorted to for the cure of them. Hence the whole of the diseases of these animals came by degrees
to be treated by farriers, who are, however, now superseded in England by a more enlightened class of veterinary practitioners.

FARRIERY. The art of preventing, curing, or alleviating the disorders to which horses and cattle are subject. The practice of this useful profession in England was, until within the last half century, almost entirely confined to a class of men who were utterly ignorant of the anatomy and physiology of the horse, &c., and the general principles of the art of healing. Their prescriptions were as absurd as the reasons they assigned for administering their boluses and drenches. But the establishment of a veterinary college, and a better educated class of persons having taken up the profession, has created a new era in veterinary science.

FARROW. A sow is said to farrow when she brings forth pigs; and the pigs brought forth are called a litter or farrow.

FARTHING-DALE. A provincial term for a stoppage or obstruction in the intestines of the cow.

FARTHING-DALE. The fourth part of an acre of land, now generally called a rood. It is sometimes written farding-dale.

FARTHING-DALE. An unctuous, solid substance, or, more properly, a concrete oil, deposited in little membranous cells in various parts of animal bodies. It is generally white or yellowish, with little taste or smell, and varies in consistency according to the relative quantities of stearine and oleine which it contains. Goats' fat, besides these principles, contains also hircine, to which it owes its peculiar smell. Different kinds of fat liquefy at different temperatures. Lard is softer than tallow, melts at 57°; but the fat extracted from meat by boiling requires a heat of 127°. The ultimate elements of animal fat are the same as those of vegetable oils. According to the analysis of Chevreul, 100 parts of human fat are composed of 79° carbon, 11° hydrogen, and 9° oxygen. Hog's lard and mutton suet are very similarly constituted. Fat is insoluble in water, alcohol, and ether. The strong acids dissolve, and gradually decompose it. With the alkalies it combines and forms soap; hard with soda, and soft with potassa. Fat serves to defend the muscles and bones against cold, to temper the acids of aliments, and to invigorate and support the whole frame.

FAT HEN. A provincial name for the wild spinach (Chenopodium album), commonly called in the United States Lamb's-quarter, and sometimes Goose-foot.

FATHOM (Sax. faeden). A measure of length containing six feet or two yards; chiefly used for measuring the length of cordage and the depth of water and mines.

FEATHER-GRASS (Stipa pennata). This is a doubtful native; it is found sometimes on dry, mountainous rocks. It is a perennial, flowering in June. The root is fibrous; stems a foot high, covered with dense tufts of long, narrow, acute, dark green, roughish leaves; sheaths striated and very long; stipules oblong, obtuse; flowers in panicles, simple, erect, six to seven flowers; awns nearly a foot long. At the time of flowering, the produce per acre from a heath soil was 9328 lbs., dry produce 3454 lbs., nutritive matter 409 lbs. This produce was taken from a heath soil that had been planted with the grass, for the wild seed does not vegetate; but it may be propagated to any extent by parting the roots. Its agricultural merits appear to be so inconsiderable as to rank it among the inferior grasses. The beautiful feather-like awns which terminate the larger values of the blossom, and adhere to the seed, serving as a sail to waft it from rock to rock, have procured it a place in the flower-gardens of the curious, and serve to distinguish it from all other grasses. The feathered awns are sometimes worn by ladies instead of feathers, which they resemble. The seed is ripe about the middle of September.

Nuttall describes several American species of feather-grass, which abound in some of the warmer portions of the United States and Territories. One species, the Juncus, grows very commonly on the grassy plains of the Missouri, as well as the Stipa Virginica, both being very troublesome when in seed, adhering by the sharp stipe to everything which comes in their way. Not a single species is useful in agriculture. In Barbary and Upper Louisiana they appear in the places the prevailing herbage, communicating to the desert plains the colouring of harvest, called parijolat by the American Spaniards. (Nuttal's Genera.)

FEATHERS (Sax. pes; Ger. feder). A general name applied to the exterior covering or plumage of birds, and by which they are enabled to fly. Feathers vary in form, size, and function in different parts of the bird, and have accordingly received distinct names in ornithological science. The quill part consists of coagulated albumen. Great quantities of goose and other feathers are annually imported into England from the north of Europe, which, however, are insufficient for the demand; hence poulterers dispose of vast numbers of the feathers of other domestic poultry, all of which are much inferior to those of geese. The feathers, after they are plucked, are generally dried in an oven. Notwithstanding every apparent caution, the feathers will frequently be found to be tainted, either from carelessness in plucking, or by neglecting to attend to them afterwards. In this case, the only method to render them sweet is to boil them a few moments in stout calico or canvass bags in a copper, and afterwards dry them in the open air. In about a fortnight, if the weather be fine, they will become perfectly sweet and ready for use.

FEBRIFUGE (Fr.) In farriery, such medicines as are beneficial in cases of fever. See Fever.

FEED (Sax. feden). The quantity of oats or grain given to a horse or other animal at one time. It also signifies to fatten animals, as cattle or sheep.

FELL. The skin or hide of an animal.

FELLING TIMBER. The act of cutting down trees for the purposes of timber. This term is only used in respect to full-grown trees, and is never applied to young trees nor to bushes, underwood, or hedges. Much has been written respecting the proper season for felling trees; some arguing in favour of mid-
winter, and others in favour of midsummer. The question principally turns upon the quantity, and the value of the soft or outer wood in the trunk of the tree to be felled, known by foresters and carpenters as the sap-wood. As this sap, or outer wood is the only portion of the trunk in which the sap or juices of the tree flow, it is evident that if no value be set upon it, the tree may be cut down at any season; because the truly valuable part of the trunk, the mature timber, is impermeable to the sap in its ascent through the soft wood, and is therefore in a state of inactivity for the next best being midsummer, when the sap is chiefly confined to the young shoots, the circumference of the soft wood and the bark. The worst time for felling timber is the spring, just before the development of the buds, when the tree is fullest of sap, and receiving constantly fresh supplies from the root; and in autumn, immediately before the fall of the leaf, when there is a superabundance of sap, from its being as it were thrown out of employment by the falling of the leaf. In general, all the soft woods, such as the elm, lime, poplars, willows, &c., should be felled during winter: hard woods, like the oak, beech, ash, &c., when the trunks are of large size, and valued chiefly for their heart wood, may be felled at any time. When the bark, however, is to be taken into consideration, as in the oak, the tree should be felled in spring, as then the bark contains four times the quantity of astringent matter to that felled in winter. See Timber and Woods. (Brandle’s Dict. of Science.)

FELLMONGER’S POAKE AND CLIPPINGS. Poake is the waste arising from the preparation of skins, and is compounded of various proportions of lime, oil, and hair. It is commonly used as a manure, in the state of compost with earthy substances, and sometimes, when it is thought expedient to increase the powers of farm manure, also with stable dung. The clippings are the parings and scrapings of the skins. When ploughed in upon a summer fallow for wheat, these clippings have been found highly serviceable to deep lommy land, and to strong soils which are not too wet, for they not only produce a full clean grain, with a bright straw, but the bulk of the crop is also greatly increased. Care should, however, be taken to cover them well with the soil, for if left near the surface, the putrid effluvia, which they soon emit, attract the crows in swarms, and great quantities are thus lost out of the ground. From thirty to forty bushels per acre is the usual quantity applied; and in the same state at every season of the year. From 4d. to 9d. per bushel, heaped loose. (Brit. Husb. vol. i. p. 423, 424.)

FELLY. A provincial word meaning to break up a fallow. It also signifies a part of a wheel.

FELON, or FETLOW. In farriery, a term for a sort of inflammation in animals similar to that of whitlow in the human subject.

FELT. A kind of stuff formed of fur or wool alone, or of a mixture of these articles with camel’s hair, which are blended into a compact texture used principally in the manufacture of hats. Hare and rabbit’s fur, wool and beaver, are the chief materials used; they are mixed in proper proportions, and tossed about by the strokes of a vibrating string or bow, till they become duly matted together. Felt strongly compressed is now used as cloth. It has one advantage over woven cloth, it does not become threadbare by use.

FEN. The name of a disisterm to which hops are subject. It consists of a quick growing mould, or moss, which spreads itself with much rapidity, and occasions great injury.

FENCE. In rural economy, is any kind of erection used for the purpose of enclosing and protecting the surface of land and another, for the purpose of separation or exclusion. The kind of obstacle or material differs according to the animals which are to be separated, excluded, or confined, and the nature of the soil and situation. In the early state of husbandry, fences were little known or wanted, except in particular places, as near houses or yards. The introduction of fences into agriculture was simultaneous with the progress of that art, as that of the principle of the division of labour into the art of manufacture. The subject of fences is one of high interest to the farmer, an immense amount of whose capital is annually expended chiefly for the purpose of preventing the depredations of stock belonging to other persons. Many valuable observations on this topic will be found in various American agricultural periodicals.

FEN LANDS, or PENS. Boggy or marshy lands, the subsoil of which is, in a state of saturation with water, and the surface liable to be overflown by rivers or streams during spring or autumn. The soil of these lands is generally black, light, and rich to the depth of two or three feet; and as the surface water readily filters through this soil to the subsoil, fen lands generally produce, when properly drained and cultivated, bulky crops of grass and corn. As they have very seldom any natural outlet for their drainage, this is usually performed by machinery; and when this is the case fen lands are more productive. (See Draining and Warping.) The principal fens in England are those of Lincolnshire, Cambridgeshire, and the adjoining counties, a very full account of which will be found in McCulloch’s Geogr. Dict., art. “Bedford Level.” (See also Brit. Husb. vol. i. p. 466–469. “On the Course of Cropping in the Pens,” vol. ii. p. 107.) Fens generally abound with saline plants, which are very nourishing to cattle. See Fens. Hotths.

FENNEL, COMMON (Mennum favaeum, Smith). This is a well-known biennial plant,
FERMENTATION.

in our kitchen gardens as a garnish. It is likewise used as a domestic medicine. The taste and aromatic qualities of the garden fennel are well known. The sweet and warm seeds are a common carminative for infants.

FENNEL, SWEET (Foeniculum dulce). This species of fennel is an annual plant, a native of Italy and Portugal, where it is cultivated as a pot-herb, as well as for the seeds and the oils which these afford. It is a smaller plant than the common fennel. The stem is somewhat compressed at the base. The fruit is much longer than that of the common fennel, being eight to ten times as long and twice as broad, somewhat curved and pales, with a greenish tinge. The turions are also sweeter and less aromatic, and the root (seed) has a more agreeable odour and flavour.

The fruit is imported, and affords the oil of fennel and the fennel water of the druggists. Both are useful in flatulent colic; and the latter is a pleasant vehicle for administering other medicines to children.

FENUGREEK (Trigonella, Fenugreek). Fenugreek is a species of trifolium sometimes cultivated in fields for its seed; but it yields a very uncertain crop, owing to the variable nature of the weather in England. The stem is a foot high, erect, with round branched stalks, trifoliate leaves, toothed; the flowers small and white; the fruit a sessile, straight, erect, some curved, acuminate, flat pod; containing a number of yellowish seeds having a strong, disagreeable smell, and an unctuous, farinaceous, and somewhat bitter taste. These seeds are very emollient, and useful in cataplasms and febrifuges.

FENUGREEK, RUSSIAN (Trigonella ru-thenica). A hardy perennial native of Siberia, blowing yellow papilionaceous blossoms in July and August. It loves a strong loamy soil, and an open situation. It is propagated either by parting the roots in spring, or from seed.

FERMENT (Lat. ferver, I boil). Any substance employed to raise or produce fermentation when mixed with or applied to another. Ferments are therefore either such substances as are naturally present in the vegetable juice, as in the grape and apple; or are added, as in the manufacture of beer and bread, where yeast and leaven constitute the ferment. Fermentation is met with in fermenting liquors of different kinds, as wine and beer, and the froth or head thrown up by them, and its principles are contained in the newly expressed saccharine juices of various summer fruits.

Ferments are of an albuminous and glutinous character; and the presence of nitrogen seems essential in their composition.

FERMENTATION. When certain vegetable substances are dissolved in water and subjected to a temperature of 65° to 85°, they undergo a series of changes which terminate in the production of alcohol or spirit; these changes constitute the phenomena of vinous fermentation. Sugar and some ferment are essential to the process, and during the formation of the alcohol the sugar disappears, and carboxylic acid is more or less abundantly evolved. The simplest case of fermentation is that of must, or of the expressed juice of the grape, which, when exposed either in close or open vessels to a temperature of about 70°, soon begins to give off carbonic acid, and to become turbid and frothy; after a time a scum collects upon the surface, and a sediment is deposited; the liquor which had grown warm gradually cools and clears, loses its sweet taste, and is converted into wine. The chief component parts of must are water, sugar, mucilage, gluten, and tartar (bitartrate of potassa). During the fermentation carboxylic acid escapes, the sugar disappears, and with it the greater part of the mucilage: the gluten chiefly forms the scum and a portion of the sediment; and the tartar originally in solution is thrown down in the form of a coloured deposit. Sugar and water alone will not ferment; the ingredient requisite to the commencement of the change is the gluten, which absorbs in the first instance a little oxygen from the air, becomes insoluble, and induces the subsequent changes. The reason why grapes never ferment till the juice is expressed, seems to depend upon the exclusion of air by the husk or membranes. In beer the alcohol is derived from the sugar in the malt. When wine is exposed to air and a due temperature, a second fermentation ensues, which is called the aseous fermentation, and which terminates in the production of vinegar. During this process oxygen is absorbed, and more or less carboxylic acid is evolved; but the apparent cause of the formation of vinegar is the abstraction of hydrogen from the alcohol, so as to leave the remaining elements in such proportions as to constitute acetic acid. Thus alcohol is theoretically constituted of charcoal, water and hydrogen, and acetic acid of water and charcoal only; the oxygen of the air, therefore, converts the hydrogen of the alcohol into water, and so effects the change into vinegar. See Alcohol and Brewing. (Brandes' Dict. of Science, &c.)

To illustrate these facts let us suppose that the following substances are put together to undergo fermentation:—300 parts sugar, 600 parts water, 60 yeast;—the products will be 771-5 parts of weak spirit, of which 171-5 is alcohol of spee. grav. 0-822; 94-6 carboxylic acid, which flies off and carries with it 41-9 of water, 12 nauseous residue, and 40 residual yeast.

Or it may be illustrated in reference to the formation of the alcohol and the carboxylic acid, which are the only real products of vinous fermentation, by the changes which take place in the chemical components of the sugar. If we take 162 parts of sugar, and 18 of water, regarding any yeast employed as merely the means of commencing the fermentation, the product should be 92 of alcohol and 88 of carboxylic acid.

Thus we see that the 73 parts of carbon of the sugar is divided between the alcohol and the carbonic acid; that the whole of the hydrogen both of the sugar and the water enter into the composition of the alcohol, and only 32 parts of the oxygen of the sugar, and none of that of the water. Fermentation, therefore, effects merely a change in the distribution of the components of the bodies subjected to its action; the yeast or ferment being the agent which effects these changes without itself entering into the products resulting from them. The yeast, if added, remains as residual matter, but where no yeast is required, that substance is one of the products of the process.

But this is only that species of fermentation which is denominated vinous. If the fermentation proceeds beyond the point which has been described, such changes, as already stated, take place; and vinegar or acetic acid is generated, and the process is then termed acetification. And the third kind of fermentation also follows in most vegetable matters, namely, the putrefactive, in which there is a large production of gases, and vegetable mould or humus. In general parlance, however, the term fermentation implies either the vinous or the acetic fermentation.

FERMENTED LIQUORS are those liquors obtained by the process described in the preceding article. See also Beer, Cider, Wine, Alcohol, &c. All liquors which have undergone the vinous fermentation are considered as great a prerogative; for it has been remarked that since the custom of brewing and distilling liquors has prevailed in Europe, many of those cutaneous and putrid diseases with which our forefathers were afflicted have been less frequent and severe than they formerly were. The total abstinence from fermented liquors by the Turks is further assigned as one of the chief causes why they are more liable to the plague and other contagious diseases, than those nations among whom beer or wine is the common beverage. (Willich's Dom. Encyc.) This opinion, however, is purely hypothetical.

FERN. An acotyledonous or flowerless class of weedy, of which there are many species in Great Britain. They grow chiefly in mountainous tracts of natural pasture. Fern is extremely difficult to eradicate, as the roots in deep soils have been found at the depth of seven or eight feet. But however troublesome this plant may prove to the industrious husbandman, it is not a weed that can be eradicated. It forms a good litter for cattle, and may be used as thatch; for though inferior to many other materials, it will last ten or twelve years. It forms a good manure for potatoes, when dug into the soil; and serves for fuel, where it is plentiful, for brewing, baking, heating ovens, burning lime, &c. The ashes, which the plant affords in great abundance, yield potash; and the poor in some districts mix the ashes with water and form lye balls for scouring linen, which are a useful and cheap substitute for soap. They are sometimes used as a fishes' dressing in hot water, and thus afford a wholesome and relishing food for all domestic cattle, which eat them eagerly, and manage to thrive and grow fat upon them.

In a botanical point of view, it would be impossible and useless to describe all the species of ferns in this work; we shall therefore notice particularly those only which are applicable to other uses than thatching, or the production of alkali from their ashes, or constituting manure, as they may all be employed for these purposes.

1. Male Shield Fern (Aspidium filix-mas) is a perennial, growing in woods, dry ditches, and on shady banks. Its roots are tufted, large, scaly; its fronds or herbage are several from one root, three feet high, doubly pinnate, erect; the midribs scaly, and the leaflets obtuse, serrated, partly confluent; the masses of seminal capsules near the midrib, and not occupying more than the half of each leaflet; and the capsular cover orbicular.

The root is nauseous, and was at one time much used as a remedy for tape worm; it indeed was the principal ingredient in the celebrated remedy of Madame Nouver, who received 18,000 francs from Louis XVI. for her secret: but since the introduction of the oil of turpentine, as a remedy for tape worm, fern root has ceased to be employed.

2. Maidenhair (Adiantum capillus veneris) is a perennial found on moist rocks and old walls near the sea. It is an elegant fern; the roots are blackish, shaggy, creeping; the fronds from 6 to 12 inches high, doubly compound; the leaflets alternate on capillary stalks, wedge-shaped, lobed, deep green, smooth, and each segment terminated in a roundish, flat scale, with the cover transversely oblong.

This fern as well as another species of the same genus, A. pedatum, is employed for making the well-known syrup called capillaire, which is, when diluted with water, a pleasant beverage in fever.

3. Fir Club Moss (Lycopodium selago). A perennial, common on the Derbyshire and Yorkshire hills, and in the Highlands of Scotland. The root is fibrous; the stem 5 to 10 inches high, once or twice forked, and level at the top. The leaves uniform, crowded in eight rows, lanceolate, obtuse, entire, slightly spreading; capsules on the uppermost shoots, kidney-shaped. See Club Moss.

The Highlanders use this fern instead of alum to fix colours in dyeing. The root is a powerful emetic and purgative; but its action is attended with giddiness and convulsions, consequently it is dangerous.

4. Greater Rough Horse tail (Equisetum hyemale). A perennial, found in boggy woods. The root is black and variously branched; the stem 2 to 3 feet high, erect, naked, rough, branching at the top, embraced by tight whitish sheaths, black at the top and bottom; and the teeth deciduous. The fruit is in a terminal catkin, and abounds with whitish powdery seeds.

This fern is well known for its use as a polisher, owing to the flinty particles (silex) deposited in the furrows of the cuticle. It is usually imported from Holland, and is therefore called Dutch rushes. (Willich's Dom. Encyc., Low's Prac. Agr.)
FERN.

FESTUCA. (Comptonia asplenifolia) is commonly found in Pennsylvania and other Middle States, where it is most abundant on dry slaty hills; but rare elsewhere. The bruised leaves emit a strong resinous, aromatic odour. The plant is used externally as a medicine. The infusion is a popular remedy in dysentery. This is the only known species of the genus Comptonia. (Flor. Celt.ter.)

FERRUT. (Mustela furo, Linn.). A useful animal, which came originally from Africa, whence it was introduced into Spain, and subsequently into England. It has red, fiery eyes; the colour of its whole body is of a pale yellow; and its length from the nose to the end of the tail is about 19 inches. The female is rather smaller in size, and produces, twice annually, from five to eight or nine young ones, after a gestation of six weeks. Ferrets are principally employed for the purpose of hunting rabbits, to which they are mortal enemies, and of destroying vermin in corn stacks and outbuildings. These animals are always kept confined in a box or cask, and fed upon bread, milk, &c.

FERRUGINOUS SOILS. Soils which contain a large proportion of iron.

FESCUE GRASSES. See Festuca.

FESTUCA. A very extensive genus of grasses, of which the meadow fescue (Festuca pratensis) and the hard or smooth fescue (Festuca durvseula, vel glabra) are those of the greatest use in permanent pasture. Combined with cock's-foot or orchard grass, and some other of the natural grasses, these two species of festuca will be found well adapted for the alternate husbandry, and secure the most productive and nutritive pasture in alternation with grain crops. Sir J. E. Smith, in his Eng. Past., observes, "that in this genus it is hard to say what may, or what may not, be a species;" and with his usual force and clearness he reduces the F. glauca, F. glabra, F. cambrica, F. durvseula, and F. rubra of Hudson, Lightfoot, Withering, Winch, and Stillling-deet, &c. into one species. All these grasses vary much from change of soil and situation; the flowers are particularly apt to vary in number as well as in the length of their awns. There is one character, however (says Sinclair), which I have never found to change under any variety of culture, which is the creeping root; and this is also an agricultural distinction which is never to be lost sight of, as it always produces a specific effect upon the soil, very distinct indeed from that of the fibrous-rooted kinds. It will be sufficient, therefore, for the purposes of the agriculturist, to consider these grasses as two distinct species, the fibrous-rooted and the creeping-rooted, noting at the same time their varieties from other parts of the plant. Following the experiments of Sinclair, in his valuable work on the grasses, I shall proceed to notice, seriatim, the different species of festuca, and point out their relative properties.

Festuca alopecuroides.—Foxtail-like fescue grass.

Root annual. Although sometimes classed as a Bromus, this grass is evidently a Festuca. From the amount of produce and nutritive powers afforded by this annual fescue, it will be found much inferior to the soft brome-grass (Bromus mollis), many flowered brome-grass B. multiflorus), and other of the annual Indigenous grasses, and it does not therefore appear suitable for agricultural purposes.

Festuca bunsae.—Wood-fescue grass. A pale, smooth, slender, insignificant grass of short duration, at least after it has flowered.

Festuca carlineus.—Red fescue grass. This species, which is too large and coarse to possess any agricultural merits, is found in mountainous woods in Scotland, Ireland, and the north-west part of England. There is a smaller variety, with much narrower leaves sometimes met with in Scotland.

Festuca Cambria.—Welsh fescue. This constant variety of F. rubra (see Smith's Eng. Flora, vol. i. p. 142) is readily distinguished from the F. ovina, and the varieties of F. rubra and F. durvseula, by the pale green colour of the panicle and culms. Experiments tend to prove that this grass is greatly inferior to the F. durvseula in the quantity and nutritive qualities of its produce.

Festuca durnetorum.—Pubescent wood-fescue grass. Root perennial, slightly creeping. This grass, which appears to belong to the inferior kinds, is a native of woods, where the soil is dry and sandy.

Festuca durvseula.—Hard fescue. Pl. 6, fig. 3. Panicle unilateral, oblong, much spreading when in flower; florets longer than their awns; stem round, upper leaves flat, root fibrous, perennial; scarcely creeping, though sometimes throwing out short lateral shoots. Stem 1½ or 2 feet high, erect, leafy, striated, smooth. The hard fescue early attains to maturity; the culms are succulent and nutritious; it grows quickly after being cropped, and springs very early. From the above details, although very deficient in the weight of produce, it appears to be one of the chief of the fine or dwarf-growing grasses. This grass is most prevalent on light rich soils; but it is also continually found in the richest natural pastures where the soil is retentive of moisture, and is never absent from irrigated meadows that have been properly formed. It attains to the greatest perfection when combined with the F. pratensis and Poa trivialis. From its property of withstanding drought in rich natural pastures better than many other grasses, added to the merits above-mentioned, this grass is entitled to a place in the composition of the best pastures, but not in any very large proportion on account of its inferior productive powers.

When cultivated on a poor silicious soil, or on a thin heath soil, the culms become very fine and slender, and promise to be valuable for the manufacture of straw hats. This grass flowers about the middle of June, and the seed is ripe late in July.

Festuca elator, var. fertilis. Fertile-seeded tall fescue grass. This is a coarse but nutritious grass, forming sometimes a considerable proportion of the crop of marsh land hay. Root somewhat creeping, with downy fibres penetrating deeply into the mud or clay. Stem about 4 feet high, reedy, striated, smooth, and leafy. Panicle a foot or more in length, repeatedly compound, spreading widely. This
Festuca.

F. This grass differs from the common variety of tall fescue in having the panicle somewhat drooping; spikelets six-flowered, more ovate and flat; the larger husks of the calyx often uncovered, and the awn is fixed on the apex more in the manner of a bract or than of a fescue. Leaves smoother, and of a less dark-green colour. For damp soils, that cannot conveniently be thoroughly drained, this would be a most valuable plant, either to be cut for soil- ing or made into hay, and reduced to chaff as it might be wanted. This grass (which is nearly allied to the common F. elatior next to be described) perfects an abundance of seed (though not entirely free from diseased portions), and is therefore not liable to the objection which takes so much from the value of that variety. It is equally early in the produce of foliage, and the nutritive properties are about the same. It flowers early in July, and the seed is ripe in the first week in August.

A species is described under the name of floating fescue (Festuca fluitans) in London's Encyc. of Agr. and there said to be found in rich swamps, especially in Cambridgeshire, England, where it is thought to give the peculiar flavour to Cheddar and Cottenham cheese. It is also found in the ditches and ponds in most parts of England. Pl. 5. f.

Festuca elatior, var. sterilis.—Pl. 5. c. Barren-seeded tall fescue. This species greatly resembles the F. pratensis, but is larger in every respect, and flowers eight or ten days later. This is a grass admirably adapted for tenacious clay soils, and might be cultivated with advantage by the farmer combined with some of the other highly productive grasses, in such moist spots of the soil as are peculiarly suited to the growth of this species, although less fitted for the growth of proper pasture grasses. It is nutritive and very productive, and one of the first grasses in the production of foliage early in spring. The produce, like that of all grasses which yield a great weight of crop, may be considered coarse when compared with the F. pratensis and Alopecurus pratensis; but this objection may be overcome by reducing the hay to chaff, and mixing it with clover-hay. The nutritive matter contains but little bitter extractive or saline matter, while the clover contains an excess. In England it flowers in the second week in July; the seed is universally affected with the disease termed clavus, and consequently unfertile; it can only, therefore, be propagated by parting and planting new roots.

Festuca gigantea.—Tall fescue grass. This species is confined to woods in its natural state; but it continues in the soil, and appears to thrive equally well when cultivated in open situations. It is a coarse grass, and but little nutritive, although greatly superior to the spiked and wood fescue grasses.

Festuca glabrata, var.—Smooth fescue. Pl. 6. a. Panicle branched, upright, compact; spikelets spear-shaped, 4-6-flowered, smooth, armed, root fibrous; perennial. This grass is closely allied to the F. tritineca and F. rubra. According to Sir J. Smith, it is a variety of the last-named. From the trials made with this grass, it seems to be inferior both in produce and nutritive matter to the F. durincula, but is superior in regard to early produce, and the herbage is uncommonly fine and succulent. These merits, however, appear hardly sufficient to compensate for the deficiency of produce. If it be compared with some of the early grasses, Asthacanthum adoratum, for instance, it will be found superior in nutritive matter in the proportion of about one-third. While this grass cannot be recommended in preference to the F. durincula, yet, among the fine-leaved fescues, it will be found the best substitute for that species when wanting.

Festuca glauca.—Glauces fescue grass. This is a native of alpine situations, but thrives better when cultivated on lower ground than most other species having the same origin. Although its merits do not appear sufficiently great to entitle it to a prominent place among the superior grasses for light soils, yet its hardy and nutritive nature, and property of forming a thick turf, prevent it from being altogether rejected as of no value. It flowers in the second week of June, and the seed is ripe about the first week of July.

Festuca lobata. Darnel-like fescue grass. Pl. 5. f. Spike two-ranked, drooping; florets cylindrical, awnless, pointed with fine slight ribs at the top. Root fibrous, perennial. At a casual glance this grass bears a near resemblance to the Lolium perenne (rye-grass), and affects the same kind of soil; but, on a more minute inspection, the calyx or outer husk so conspicuous in the spikelets of the rye-grass, in this grass will be found almost wanting. Another mark of difference is, that in the rye-grass the spikelets are arranged so as to stand facing the spike-stalk; while in the darnel-like fescue they stand with their backs towards it. This grass possesses all the valuable properties of rye-grass, and few of its defects. Its produce is larger; it springs earlier and improves by age, which is not the case with common rye-grass. It would, doubtless, be the best substitute for that species in alternate cropping; but, unfortunately, it does not perfect a sufficient seed, the flowers generally proving abortive, which renders its propagation inconvenient and expensive. In rich meadows this grass is very common, particularly where the land is periodically overflowed.

Festuca myuros. Wall-fescue, Capon’s tail-grass. Panicle drooping, elongated, rather close; florets tapering, shorter than their awns, rough at the top; awn-awned; stem leafy to the very summit. It is, perhaps, the “trembling rye-grass” of poets. Root annual. The flowers have only one stamen, which distinguishes it from all other species of fescue. This grass has great affinity to the barren fescue (F. bromoides), but the whole plant is larger and stouter, the stem clothed with leaves to the top, and the panicle four times as long. The inner valve of the blossom is fringed towards the top; the awns are longer than those of the F. bromoides. This grass is found on walls, and dry, barren commons. As soon as the seeds are ripe, they fall out of the husks, and vegetate quickly after, without any covering of earth. The plants are of the finest green colour, and retain their verdure during the winter.
FESTUCA.

This circumstance seems to have led to the supposition that it was a biennial grass. The seeds being numerous, the young plants form a most beautiful dark green turf, surpassing, in this respect, every other grass. But this property declines with the spring, when the growth of other grasses becomes more general; and before the time of flowering it is invariably attacked with the rust, which renders its produce of small value, even were it afforded in a quantity sufficient to induce its cultivation. It flowers in the first week of July, and the seed is ripe about the last day of that month. Birds appear to be very fond of the seed.

Festuca ovina. Sheep's-fescue-grass. (Pl. 6, k.) Panicle small, erect, unilateral, rather close; florets four or five, nearly cylindrical, pointed or awned, smooth at the base and at the edges of the inner valve; stem from 6 to 12 inches high, erect, slender, rather rigid, smooth, leafy below, square in the upper part; leaves very numerous, composing dense tufts, folded, bristle-shaped; stipule very short and obsolete; root fibrous, perennial. The awns appear to be an uncertain character in this grass, as it is frequently awnless, and there are varieties of it having awns. All the varieties, however, may be distinguished at first sight from the F. duriuscula, glauca, rubra, &c., to which it is nearest allied, by the compact though simple appearance of the panicle, which more distinctly faces one way.

Linnaeus affirms that sheep have no relish for hills and heaths that are destitute of this grass. Emelin, in his Flora Siberica, also informs us that the Tartars select places for pasturage during the summer where this grass is in the greatest plenty, because it affords a most wholesome food for all sorts of cattle, but chiefly sheep. Dr. Anderson, in his Agricultural Essays, affirms that it is capable of affording an immense quantity of hay. Mr. Curtis, however, in his Practical Observations on British Grasses, very justly combats this opinion, and asserts that it is more fitted for forming grass-plats; but even for this purpose it will only succeed on soils which are nearly as dry and light as that on which it is spontaneously produced. From trials which have been made, the sheep's fescue does not appear to possess the nutritive powers usually ascribed to it. It has, however, the advantage of a fine and succulent foliage, and may, on that account, be better adapted to the masticating organs of sheep than the larger grasses, whose nutritive powers are greater. Hence it may be of some value as a pasture for sheep in situations where it grows naturally. In England it flowers in the third week of June, and ripens the seed about the last day of July.

Festuca ovina hordeiformis. Long-awned sheep's-fescue-grass. (Pl. 6, i.) Panicle compound; branched, crowded, 6-10-flowered. Root-leaves thread-shaped, stem-leaves very long. Root fibrous, perennial. This grass is much superior to the F. ovina, of which it is considered a variety. It flowers earlier than any of the other fescues, and appears to possess sufficient merit to entitle it to a place in the composition of the best pastures, particularly as a substitute for the F. duriuscula, on soils of a drier or sandy nature. Its nutritive qualities are nearly the same as those of the F. duriuscula, but it is superior to that species, and to most others, in the produce of early herbage in the spring; and the herbage is very fine, tender, and succulent. The culms are well adapted for the manufacture of the finest straw plait, being very distant in the joints, and of an equal thickness throughout. In England this grass flowers in the last week of May, and the seed is ripe in June.

Festuca pinnata. Spikelet fescue-grass. This grass grows chiefly in dry, hilly woodlands, particularly where the soil is calcareous. It cannot as yet be considered in any other light than a noxious weed; for, though the weight of the produce is considerable, it is neither early, nor nutritious, nor relished by cattle. This, and the F. sylvestris, which is also an inhabitant of woods where the soil is silicious, may be considered the least useful of the British grasses. It flowers about the third week of July, and ripens the seed late in August.

Festuca pratensis. The meadow or fertile fescue-grass. Panicle nearly upright, branched, spreading, turned to one side; spikelets linear, compressed; florets numerous, cylindrical, obscurely ribbed; nectary four-cleft; root fibrous, perennial. Dr. Withering makes this grass a variety of the F. elatior; but it is more justly made a distinct species by Sir J. E. Smith. It differs from the F. elatior in being only half as high, the leaves only half as broad, and the panicle shorter, and containing only half the number of flowers. The panicle is but once branched, droops but slightly, and leans to one side when in flower, and the flowers grow all one way. In the elatior the panicle branches both ways, it droops much at first, and the flowers grow more loosely; the spikelets are rounder, ovate, and pointed, while in the pratensis they are somewhat linear, flat, and obtuse.

The F. pratensis is eaten by horses, cattle, and sheep, which are all very partial to it. In point of early produce in the spring, this grass stands next to the meadow foxtail (Holcus pratensis), and is superior in this respect to the cock's-foot.

The meadow fescue constitutes a very considerable portion of the herbage of all rich natural pastures and irrigated meadows; it makes excellent hay, and though a large plant, yet the herbage is succulent and tender, and much relished by cattle, as it does not form rank tufts like the larger grasses. Although essential for permanent pasture, yet this grass is not by itself very well adapted for the alternate husbandry, but should be combined with cock's-foot, rye-grass, and rough-stalked meadow-grass. The F. pratensis is not so abundant in the deep alluvial soils of Lincoln as in the clay districts. In the vale of Aylesbury it constitutes a considerable portion of the most valuable and fattening pastures of that rich grazing district. Mr. Tauntson's experience of this grass, grown on a stiff, clayey soil, proved that a copious crop of seed-stalks may be obtained the second year from sowing. In England it flowers in June, and ripens the seed late in July or early in the following month.
FESTUCA.

Festuca rubra. Creeping or purple fescue-grass. There are two varieties of this species; one with narrow bristle-shaped root-leaves, and the other with broader leaves. It has much affinity to the F. duriscula, from which it is however distinguished by the leaves, which are broader and longer, and the branches of the panicle are also longer.

The creeping fescue has no sufficient merit over those species it resembles in habit to compensate for the impoverishing effects of its roots to the soil.

Festuca sylvestris. Slender wood fescue-grass, or the wood-branched grass of some botanists. The general appearance of this grass promises but little to reward the labours of the experimentalist.

Festuca uniglumis. Single-husked fescue-grass, found on the sandy sea-coast, chiefly of Sussex; it possesses no agricultural merits, and Sinclair does not even notice it.

Festuca vilipars. Viviparous fescue-grass. The roots, leaves, and general habit nearly agree with the F. ovina, of which most botanists have esteemed this a variety. This grass forms a curious exception to the general law of nature in the propagation of plants by their seed. It has every part of a flower, except the two most essential ones, for its propagation, namely stamens and pistils. Yet from this imperfect flower it produces perfect plants. The rudiment of the future plant originates in the upper floret of each spikelet, and in its first stage appears like a minute globule of water, scarcely visible to the naked eye; but after the spike is developed, it gradually assumes an oblong figure, becomes pointed, and at last puts forth a single leaf, after the manner of perfect seed of grasses; other leaves succeed to this, till the weight of these (now a perfect plant of grass, except the root) forces it to fall from the spike to the ground, or bends down the spike, where it soon strikes root. This grass continues viviparous on all soils. Many other grasses are viviparous, as Alopecurus pratensis, Cynoglossum crispatum, Poa alpina, Phleum pratense, Anthoxanthum odoratum, &c.; but in these the seed is first perfected, and merely vegetates in the husk from accidental circumstances, such as growing in shaded places, and from long continuance of moist warm weather.

This grass, which is natural to alpine situations, can only be propagated by parting the roots, or by planting the young plants formed in the ear. But from the trials that have been made of it, it appears to have no excellence that can recommend it to the notice of the agriculturist.

The species found in the United States, are,

1. F. teffello, little, or slender fescue, frequent on dry sterile banks, and the borders of woods, a slender, wiry little plant of little or no value to the farmer, and generally confined to poor soils.

2. F. clitor, or Tall fescue, a perennial, found frequently in swampy meadows and low grounds, flowering like the former in June and July. According to Dr. Darlington, this species, which he supposes to come from Europe, is a larger plant than the slender fescue, to which it is nearly allied, but not so valuable.

3. Meadow fescue, a much more valuable grass, according to Dr. Darlington, than the F. clitor, to which it is so closely allied that it may be doubted whether it is more than a variety. It is a naturalized foreigner that has found its way into all the best meadows and pastures of the Middle and many other States of the Union.

4. Nodding fescue (F. nutans) found in moist woodlands. It is not a grass of much value, being rather solitary in its habits, and chiefly confined to woodlands. Eight or nine additional species of fescue have been described in the United States. (See Darlington's Flor. Cestrica; Nutall's Genera.)

FEVERFEW. (Pyrethrum; from pyr, fire, the roots being hot to the taste). Of this interesting European genus of plants, the Matricaria of Linnæus, three species only are indigenous to England.

1. The common feverfew (P. parthenium), a biennial which grows in waste grounds, hedges, and walls, flowering in June or July. Root tapering, small, and white; stem erect, branched, leafy, round, many flowered, about two feet high; leaves stalked, of a hoary green, pinnatifid. Flowers numerous, like daisies, white or yellowish, in a corymbose panicle, sometimes compound, on long naked stalks, erect, about half an inch broad. The whole plant has a strong disagreeable smell, a bitter taste, and yields a volatile oil by distillation. It was formerly reckoned tonic, stimulating, and anti-hysterical, and the oil is still regarded as such. It contains much tannic acid; and in Germany it has been usefully employed in tanning and currying leather.

2. The corn feverfew, or scentless May weed (P. inodorum), is very common in cultivated fields, and by waysides, on gravelly soils. Root tapering, rather large, annual, flowering in August or September. Herb nearly destitute of the peculiar agreeable or disagreeable odours of its tribe. Stem branched, spreading, leafy, angular, smooth. Leaves sessile, pinnate. Flowers as in the last. The seeds crowned with a membrane, the best diagnostic character of the species.

3. The sea feverfew (P. maritimum), a perennial, flowering in July or August, is found on the sea coast in sandy or stony ground. The thick, woody, long-enduring root runs deep into the ground, producing a number of hollow stems, spreading circularly on the ground, often tinged with purple. Leaves crowded, sessile, doubly pinnate, of a dark shining green.
FIAR. crown of the seeds lobed; stem diffuse. Flowers not quite so broad as those of *P. inodorum*. The whole herb is slightly aromatic.

The common wild chamomile (*Matricaria chamomilla*, Pl. 16, *w. w*.) was formerly classed as a feverfew. The greenhouse kinds of feverfew grow in any rich light soil, and young cuttings root readily when planted under a glass. Any common soil suits the hardy kinds, which are increased by divisions or seeds. It possesses the properties of the real chamomile in a marked degree, and might be substituted for it as a medicinal agent. (*Eng. Flor.* vol. iii. p. 451.)

FIAR. A word of Gothic origin, applied, in the northern parts of Great Britain, to certain averaged returns of the prices of grain for the current year in the different counties, which are fixed by the sheriffs respectively, with the assistance of juries, in the month of February. When the jury has been called, evidence of the prices of the different grains raised in the county must be laid before them: and the averages struck by the jury and sanctioned by the judge are termed *fior* of the year in which they are struck, and regulate the prices of all grain stipulated to be sold at the fair prices. These fior also regulate (where no price has been otherwise agreed upon) the contract price upon delivery for grain grown in the county. Having the prices of grain, &c., ascertained in each county has greatly facilitated the introduction into Scotland of the practice of letting land for corn rents, convertible at the prices of the day. In England, where there are no such authentic local returns, there is great difficulty in converting corn rents into money rents, as reference can only be made to the prices of some particular market, which would be too limited a criterion, or to the kingdom at large, which, on the other hand, would be too extensive.

FIELD (Sax. *pell*; Germ. *feld*; Dutch. *veld*). A portion of land enclosed by a fence, or rendered distinct by some line of separation, and set apart either for tillage or pasture. In former times, and until within the last two centuries, almost all the land cultivated with the plough throughout Europe was unclosed; and the term "field" was then applied, in Britain at least, to the lands under culture by the plough. Subsequently, when farmers enclosed any portion of a lands near the farm-yard these portions were called *fields*, and the more distant portion which remained open was called open field, or common field, while grass lands unclosed were called commons. In the present improved state of agriculture, every farm is divided into fields, either simply by lines of demarcation, which are sufficient when no animals are to be grazed on the field, or by lines of separation which will act as fences, such as walls, hedges, ditches, &c., where cattle are to be grazed. Each field, on a farm, is usually known by a particular distinguishing name. Without some regular fixed division of arable lands, it would be next to impossible to conduct a rotation or succession of crops. It is interesting to observe that, as agriculture in a rude state had no fences, so this is also beginning to be the case in agriculture in its most refined form; because it is found much more advantageous, both for the production of butcher's meat and manure, to consume the grass and herbage grown on farm-lands in farm-yards, with the single exception of that portion which is eaten by sheep; and these are now often merely confined to successive portions of grass and other green crop lands by light netting or hurdles, scarcely visible at a short distance. (See *Folding*. By thus getting rid, to a more considerable extent, of fences of every description, from a tenth to a fifth will be added to the contents of the greater number of corn-farms; and a very considerable first cost and annual expense will be saved in planting hedges or building walls, and in keeping them in repair afterwards. (*Bramle's Dict. of Science*, &c.)

FIELDVOLE (*Aerecula agrestis*). A name of the short-tailed field mouse or meadow mouse; a species which subsists exclusively on vegetable productions; and being, like the rest of the rat tribe, extremely prolific, multiplies occasionally to such a degree, even in England, as to become the most injurious of wild quadrupeds. "After having followed the labours of the reaper, and taken their share of the harvest," the fieldvoles, says Mr. Bell, "attack the newly-sown fields, burrowing beneath the surface, and robbing the husbandman of his next year's crop, and at length, retreating to the woods and plantations, commit such devastations on the young trees as would scarcely be credible, were not the evidence too certain to be doubted. In the years 1813 and 1814, these ravages were so great in the New Forest and the Forest of Dean, as to create considerable alarm, lest the whole of the young trees in those extensive woods should be destroyed by them." A timely and assiduous attention to restraining the increase of this pernicious species, by the aid of terriers, ferrets, and traps, is imperative on those who have the charge of young plantations; but when the numbers of the fieldvole have surpassed the usual bounds, then it is recommended to dig holes about a foot in depth, and the same in diameter, taking care to make them much wider at the bottom than at the top, so that the animal once in cannot easily get out again. In holes of this kind, Mr. Jesse states that at least thirty thousand fieldvoles were caught in the course of three or four months in the Forest plantations; that number having been counted out and paid for by the proper officers of the forest. (*Bramle's Dict. of Science*).

FIG (*Ficus*). The genus to which the common fig tree belongs is of considerable extent; and its species are among the most noble objects belonging to the vegetable kingdom. In tropical countries the trees which yield caoutchouc (India rubber) of the finest quality belong to this species, particularly *F. clusia*. The celebrated ban-yan tree (*F. religiosa*) of India is a kind of fig tree. It is remarkable that the common fig tree (*F. carica*), although it produces so agreeable a fruit, is in some measure poisonous, particularly the milky juice which exudes from the leaves and the
branches when wounded, and which is acrid to the taste. The fruit of the fig tree is of a different nature from the orange, apple, and other fleshy seed vessels; being a hollow receptacle, containing a multitude of minute flowers; the ripe fruit of which is the seed, as it is wrongly called, that is imbedded in the womb. The fig is indigenous to Syria and Barbary, and also in the habits of southern Europe; according to the *Hortus Kewensis*, it was first planted in this country in 1548. The varieties in fig countries are almost as numerous as those of the grape. Those held most in esteem in England are the brown chestnut-coloured Ischia, the black Genoa fig, the small white early fig, the large white Genoa fig, the black Ischia, brown and black small. Italian figs, the Malta fig, the Murrey or brown Naples fig, the green Ischia, the Madonna, the Brunswick or Hanover fig, the common blue or purple fig, the long brown Naples fig, the small brown Ischia fig, the yellow Ischia fig, and the Gentile fig. According to Forsyth, the figs proper for a small garden are the large white Genoa, the early white, the Murrey fig, the small brown Ischia, and the black Ischia. Figs may be propagated from seed, cuttings, layers, suckers, roots, and by ingrafting; the most generally approved method is by layers or cuttings which come into bearing the first or second year. Standard fig trees require protection during winter, and should be covered with matting, reed, pease-haum, straw, or any other light covering.

The only orchards of standard fig trees in England are at Tarring and Sompton, near Worthing: the produce is great, and the figs of a very superior quality. The fig has been analyzed by Bley, and found to contain the following substances, 62.5 of sugar, 0.9 fatty matter, 0.4 extractive with chloride of calcium, 5.2 gum with phosphoric acid, 1504 woody fibre and seeds (*achene*). Figs are nutritious and laxative. The oldest cataclysm on record was composed of figs. In the illness of Hezekiah, Isaiah said, "Take a lump of figs; and they took and laid it on the boil, and he recovered." (2 Kings, chap. xx.; London's Ency. of Gard.; Brande's Dict. of Science.) The cultivation of the fig has been too much neglected in the United States. In the Middle and more Northern States they require protection in winter. With a good soil and plenty of water in the summer the yield of this wholesome fruit is great.

**FIGWORT (Serophalaria).** There are, in England, four kinds of indigenous figwort, all perennial; the species found in the United States is called *S. marylandica*, Maryland S. or Carpenter's Square: it is perennial, frequent in fence rows, woodlands, &c. The root bruised into the form of a poultice, is a popular application to boils and other inflammatory gatherings. One or two varieties of this plant are also met with (*Elor, Cestria*.)

**FILBERT, or PILBERD (Corylus avellana*, so named from Abella or Avella, a town of Campania, where the best were cultivated. Pliny, b. xv. c. 22). In England the best known varieties of the filbert are the white, the red, and the frizzled. The white is the kind most commonly grown. In the neighbourhood of Kent many hundred acres are planted with filberts, for which the county is celebrated, and whence the London market is principally supplied. When quite ripe, filberts will keep for several years in a dry room; and if the air is excluded, or the nuts placed in an air-tight jar, they will keep good and retain their flavour for an indefinite period.

In a late number of that excellent Journal, the *Boston Magazine of Horticulture*, &c., there is a paper by Mr. Downing, of Newburgh, N. Y., on the cultivation of this nut. From the great quantities annually imported, there can be little doubt a ready market would be found for the product of a filbert garden or orchard, and the ease and certainty with which they may be grown, should recommend them to favour. Mr. Downing recommends a soil naturally dry rather than moist, but a dry gravelly loam or sandy loam is preferable. They will succeed, however, in any good soil. The kinds preferred by Mr. Downing for cultivation in this country, are the Cosford, Frizzled, and Northampton prolific. There are other varieties, but these have been well tested, and will abundantly repay the grower. The cultivation of such nuts is a great object in some parts of England, and the average crop is considered about 800 lbs. per acre, though at times, when the soil and season is favourable, more than three times that quantity have been gathered. There are two species of the filbert found in the United States. One of these (*Corylus Americana*) is very commonly found in the Middle States, growing wild along the borders of thickets, fence rows, &c., flowering in March and April. It grows to the height of 4 to 6 feet, and the nuts, which it bears very abundantly, are pleasantly flavoured, though considerably smaller than the European hazelnuts.

**FILLER, or THILLER.** A term provincially applied to the horse which is fastened immediately to the cart, and which supports the shafts. It is most commonly written thiller.

**FILLY.** A young mare, or female of the horse kind.

**FILMY-FERN, TUNBRIDGE (Hymenophysillum Tunbridgense; from hymen, a membrane, and phyllon, a leaf; alluding to the leaves). The genus to which this species belongs ranks among the most elegant of the ferns; it is a native of wet mossy rocks or trunks of trees, most plentiful in tropical countries. This species is the only one of European growth, and flourishes amongst moss in watery shady places, in the rocky or mountainous parts of Great Britain, and grows in most parts of Europe from Norway to Italy.

**FIN.** A term applied to the sharpened or cutting plate, fixed upon a sock or couler of a plough. It is also a provincial name for the troublesome weed called Rest-harrow.

**FINCHED, or FINCHBACKED.** A term signifying streaked with white in cattle.

**FINGER GRASS, COCK'S-FOOT (Digitaria sanguinalis, from digitus, a finger; the head is divided so as fancifully to resemble fingers).** Pl. 7, f. This must not be confounded with the *Dactylis glomerata*, cock's-foot or orchard grass.
FIRES.

It is an uninteresting native wild grass, found in sandy cultivated fields, in England, but not common; like all other plants it is variable in its places of growth. Leaves broad, pointed, striated, wavy at the edges, besprenkled, like their long swelling sheaths, with little warts, many of which bear bristly hairs. Flowers in pairs, dark purplish, erect.

FINGERS AND TOES. The common name for a disease in turnips. See Asbury.

FIORIN GRASS. A name under which a variety of the long creeping bent (Agrostis vulgaris, or stolonifera, var. latifolia) was introduced about 27 years ago by Dr. Richardson, of Clonfesale, in the county of Tyrone, Ireland. (Pl. 5, n.) That gentleman laboured with great zeal, by his writings and practice on a large scale, to prove the superiority of this grass over every other for meadow purposes. One of his modes of propagating fiorin was to plant the stolons of the grass, which are as vivacious as those of couch grass, on fallow ground, and thus create a meadow; but his favourite system was to encourage its spontaneous growth on alluvial and flat peaty ground. Unquestionably Dr. Richardson did exhibit extraordinary crops of fiorin on the level surface of denuded and cut-out bog land of little value, and for several years mowed enormous crops. Fiorin, being one of the indigenous grasses of Ireland, especially on peaty soil, is seen abundantly on the black shallow bogs which have been drained in any degree, and particularly on the margins of pools and ditches. Cows relish it much if it be not soured by stagnating water, and yield milk abundantly when fed upon it. However, though it has produced from six to ten tons per acre when top dressed and preserved from the poaching of cattle, the attempt to keep any land under the occupation of this grass for meadows, to the exclusion of all others, has been totally abandoned. Two great objections to fiorin are, the difficulties of mowing it, as it lies flat and entangled, and of saving it at the very late season when it is ripe, for the scythe. Some leaves very erroneously describe the Agrostis alba as fiorin, and add, "it sometimes passes under the name of black couch grass." I am surprised that any person of experience should mistake fiorin for black couch grass (though the Woburn reports make a similar remark), to which it scarcely bears any resemblance, and from which in some respects it is essentially different. Fiorin is a soft silky-like grass, with a very narrow or linear leaf; and, although rough on both sides, yet its creeping, throwing out roots with its joints under the surface: it is very easily pulled out, and has not those knotted and vivacious roots which characterize black couch. The varieties may sometimes be mistaken for one another, but the different species have always some broad distinguishing marks of difference. As it is of great importance to the farmer to be able to distinguish fiorin from the other species of bent grass, which are unprofitable and pernicious weeds, I will here point out a few distinguishing characteristics. In fiorin the body of the seed is covered with the husks of the blossom, which do not open: it is cylindrical, but tapers to a point at each end. The seed of the clayey couch grass (A. alba) is very slender and smooth, one half the size only of the fiorin, and more slender than the A. vulgaris. The seed of the A. canina is furnished with a jointed awn of a brown colour, which readily distinguishes it from the other species. There is an awnless variety of the A. canina which is distinguished by being shorter and more plump than the fiorin of the clay couch bent. The seed of the A. fusca is not one-third of the size of that of the fiorin, more rounded at the bottom, and of a light straw colour. The A. palustris has seed about one-fifth shorter than that of the fiorin, of a lighter brown colour, and more plump and rounded. The variety of fiorin called arestata has an awn which distinguishes it at once from the seed of the more valuable variety. The distinguishing characters of the different species of agrostis are well set forth in the late Mr. G. Sinclair's valuable work on grasses; but it would rather tend to perplex than to adduce any further notice, which must necessarily be a mere abridgment. See Agrostis. (Hort. Gram. Wob.)

FIRE-BLAST. A term of very doubtful meaning, like the word blight, but generally implying an accident to which hops are very liable: it usually occurs in the month of July, and sometimes scorches up whole plantations from one end of the ground to the other, when a hot gleam of sunshine has come immediately after a shower of rain; while at others it only affects them partially, or in a particular portion of the plant. When the lower leaves of hops are shrivelled up and unhealthy, they are said to be fire-blasted. This is stated to arise from the want of sufficient nourishment in the root, the whole supply of the sap juice being required to complete the growth of the hops on the top of the pole, but little can return to the lower leaves: this is particularly observable when the hops are ripening, on those hills which have too long a pole put to them. (Brit. Hgl. vol. ii. p. 354; The Hop Farmer, p. 53.)

In the United States, the term fire-blast is generally used to designate that destruction so often witnessed in the branches of the apple, and especially the pear tree. For the discovery of the cause and remedy for this blast or blight, agricultural and horticultural societies have offered the highest premiums, which as yet have never been awarded.

FIRES. Sax. ryp. In England, the legislature has wisely afforded very considerable facilities to the insurance of farming stock. The Farmer's Insurance Institution insures at 1a. 9d. per cent., without the average clause; thus easily repaired are the ravages of the incendiary, of accidental fires, and lightning.

Causes of Fire. Mr. J. Murray has recently published a letter in a Liverpool paper on the frequency, causes, and prevention of fire, which contains many facts well worthy of attentive consideration. Among other observations, he says: "There is far too little attention paid to the locomotive engine on our railways. The ignited coals that fall below are often blown to considerable distances, carried into the adjoining
FIR.

and may, in contact with farming
stock, prove a serious evil; and I have wit-
nessed brushwood and tufts of grass consumed
by this means. A green taper, coloured as it
is by means of oxide of copper, when blown
out, acts on an aphlogistic principle, and may
continue to the end of the coil in an ignited
though flameless state, and, in contact with
combustible materials, may prove seriously-
destructive. It has certain a mahogany table on
fire—provocatively discovered in time. Damp
rags, en masse, may spontaneously take fire,
and have consumed the premises. Linseed
and other oils, but especially that of linseed,
have been the fruitful sources of conflagration
in cotton factories and the warehouses of the
merchants. Nets dipped in oil, and cast over
the rafters in an outer shed, set them on fire;
and a bale of cotton wool burst into a flame
from linseed oil being poured upon it. Even
animal matters, such as woolen, under such
circumstances, come within the precincets of
danger, I find that strong red flaming nitrous
acid will set fire to straw; and an accident of
this kind once occurred to myself. The vapour
of sulphuric ether, instead of being volatile,
and ascending, as is generally supposed, falls
to the ground like water; and accidents in the
laboratory and shop of the druggist, from igno-
rance of this fact, are by no means unfrequent.
I am personally acquainted with three distinct
cases, wherein the premises were set on fire
originating in this source. Speccs or bull's
eyes in window glass may, on the principle of
burning lens, ignite inflammable substances
brought within the limits of their focus; hence
the curtains used in some factories may be
easily ignited: thus, too, a water-bottle left in
a window may in sunshine be the means of
setting premises on fire, especially in a house
shut up during the absence of the family; and
I have seen a silk curtain consumed to tinder
by the concentrated rays of the sun, in passing
through the show-bottle in the druggist's win-
dow. Spirits of turpentine will inflame if
poured out in the hot sunbeam; and I am in-
formed by the distillers of tar and turpentine
that the head of the still cannot be safely re-
moved for 30 hours after the fire has been ex-
tinguished, as an explosion might be otherwise
anticipated. Lucifers, or Congreve matches,
are one of the fruitful sources of fires. Those
that are called Dutch, containing phosphorus,
and having a very forkid phosphoric smell, are
exceedingly dangerous: they may be igniti,
suddenly at the temperature of summer heat;
and it may now suffice to say that a recent
conflagration has been traced to this cause.
The cigar and the pipe are pre-eminent sources
of modern conflagration; and I have no doubt
that of the seat of the Marquis of Londonderry,
and the late one of York Minster, are entirely
attributable to the pipe or cigar used by the
workmen engaged in repairs. It is not gene-
 rally known that tobacco contains nitre, and
that, like "touch-wood," it may continue burning
for hours. Fires occurring from this cause
are, I apprehend, too notorious to need specific
detail. It is clear that the end of a cigar drop-
ped among wood shavings might be fanned
into a flame by a current of air; and tossed
from the top of the coach into an adjoining field,
and carried by the breeze into a farmer's stack-
yard, hay-ricks and wheat stacks may even
burst into a flame. I believe many a cigar
smoker is an unintentional incendiary."

Fires in farm yards, also, may originate from
quick lime left in a cart under a shed, and
moisture getting to it. Heat sufficient to cause
combustion is developed. The spontaneous
combustion of haystacks from the dampness
of the hay, is a danger to which the negligent
farmer is often exposed. In our present state
of chemical knowledge it is idle to attempt
to follow this phenomenon through its course,
or explain the reasons for the heat produced in
fermentation. As water must be present in
fermentation, it is probable that it is decom-
posed, and it is commonly said that the flame
produced is the result of intense chemical
action; but, as Dr. Thomson remarks (System
of Chem., vol. iv. p. 354), "All the phenomena
of fermentation lay for many years concealed
in complete darkness, and no chemist was
bold enough to hazard an attempt even to ex-
plain them. They were employed, however,
and without hesitation too, in the explanation
of other phenomena; as if giving to one pro-
cess the name of another of which we are
equally ignorant, could, in reality, add any
ting thing to our knowledge."

FIRE-WEEP (Hieracium-laced Scenico). An
American plant with an annual root, growing
in moist grounds, and remarkable for its preva-
ience in recent clearings, especially in and
around spots where brushwood has been
burned, from whence it derives its popular
name. The stem grows 2, 4 or 5 feet high, stout,
succulent and tender when young, more or
less hairy, sometimes nearly smooth. Flowers
whitish. (Flor. Centria.) See Alkali.

FIRING. In farriery, an operation perform-
ed on different parts of the horse, but which is
growing into disuse. It is principally resorted
to in cases of derangement. In firing about the
sinews and nervous parts, great care should
be taken not to go too deep, for if the fire once
touches the sinew the horse will go lame for
life. Firing is sometimes resorted to in cattle,
in order to remove bony tumours about the
region of the eye, which incommode or obstruct
the vision. In general, this operation is per-
formed in a manner calculated to excite great
pain to the horse. When the iron is white hot,
and is rapidly applied, the life of the part is
instantly extinguished, and all sensibility being
destroyed, no pain, except when the iron is ap-
proaching the part, is experienced; but much
pain follows the application of an imperfectly
heated iron.

FIRKIN. A measure of capacity in Eng-
land, being the fourth part of a barrel, or con-
taining 9 ale gallons, or 7½ imperial gallons
that is, 2528 cubic inches.

FIR, SCOTCH. See PINE.

FIR TREE (Lat. Abies; Sax. Yuh: Welsh,
lyr: Irish, lir). "The fir, the pine and the
larch," says Mr. Baxter, "constitute a perfectly
natural genus or family, and, next to the oak,
are the most valuable of our timber trees; but,
independently of their value in this respect,
their beautiful foliage and magnificent appear
ance have at all times rendered them objects of admiration and attention. They constitute the greater part of the natural order Coniferae. The term fir is often indiscriminately applied both to the fir and the pine, or Abies and Pinus, and hence we frequently hear the Scotch pine improperly called the Scotch fir, by those who are unacquainted with botanical nomenclature. The most obvious and ready character of distinction between the different genera Abies and Pinus is to be found in the natural arrangement of the leaves. The firs (Abies), have the leaves solitary, or issuing from one scale or sheath on the bark of the branches, over which they are scattered. The catkins of male flowers are also solitary, not racemose; the scales of the cone are imbricated, and thin at the apex, and are all turned to one side. They are further distinguished from the pine by their more pyramidal form. The spruces have also the leaves growing singly round the branches, and all spreading equally.

The larches have the leaves growing in clusters, which are deciduous. The cedars and pines have from two to five leaves issuing from one sheath at their base, growing also in little bundles or tufts, but they are evergreen. Of these four natural tribes, into which the firs resolve themselves, the silver fir may be taken as the representative of the first, the Norway spruce of the second, the Larch of the third, and the Cedar of Lebanon of the fourth. As all the others are noticed under their separate heads, we have only to confine our attention in this place to the firs. One property is common to all the species of this genus, that of affording resinous matter, either from the wood, bark, or cones.

The silver fir (A. picea, or pectinata) is grown in England for ornament generally. The name of silver fir is derived from the colour of its leaves on the under side, which are shorter, broader, and set much thicker on the spray than those of other firs and pines, and have a beautiful silvery appearance when the under side is viewed, or when the wind turns the branches from the eye; whilst the upper surface is of the brightest and handomest green of all the species of fir. It is a fine majestic tree, and the most beautiful, but at the same time the most delicate, of the fir tribe usually cultivated in Britain. This tree is very rapid in its growth, and soon attains to a great size; but the timber is not so valuable as that of the pine and the spruce fir. It yields, however, Burgundy oil (hence its name of picea) and Strasburgh turpentine; and is much used on the Continent both for carpentry and ship-building. The silver fir likes a deep soft soil, and a sheltered situation. From its extreme tendency to lose its leader it does not appear to be well suited for exposed grounds. Some of the finest trees in England are in the vale of Mitcham, between Dorking and Guildford, where the soil is nothing more than a deep soft sand lying on chalk. The well-known disease of the larch, commonly called American blight (see this head), or plant lice, proves fatal to the silver fir. Col. Miller says he has cured the disease with a wash of lime-water; but recommends, in advanced stages of the disease, free and early pruning. This doctrine may stave many wood growers; but the Colonel, in proof of the soundness of his opinion, adds, that he has adopted it successfully for many years. No large branch should, however, be removed when the tree is near maturity. The Swedes and Norwegians prune their trees freely, and hence the reason why they produce such a large quantity of sound timber, and are so free from knots. A weak solution of spirits of turpentine and tobacco liquor appears to be a useful wash for the disease.

2. The balm of Gilead fir (A. balsamea). This is also a delicate ornamental tree, but it rarely attains to any considerable size. This species and the silver fir are often confounded, but may be distinguished thus: "the leaves of the silver fir are arranged nearly on opposite sides of the branch, comb-like. The under sides of the leaves have a white like running lengthwise on each side of the mid-rib, which gives them a silvery hue. The leaves of the balm of Gilead fir are shorter, blunter, and stand nearly upright in double rows, on the upper side of the branches; while in the silver fir they are flattened and irregularly single-rowed." The balm of Gilead fir is so called because the clear transparent turpentine which is obtained from the wounds of this tree is very similar to the true balm of Gilead of the shops, which is the production of the Balsamodendron Gileadense. It commonly passes under the name of Canadian balsam. The wood of this tree is of a pale yellow colour, and but slightly resinous; its principal use is to split up into staves for fish barrels, for which the wood of some of the other species is much preferable.

3. The Norway or spruce fir (A. excelsa), when standing singly, with its regular pyramidal figure, and its long drooping branches reaching to the ground, forms a beautiful object; but it does not thrive well generally in the open exposed situation, and prefers the moist and springy places, and likes a deep soil. The spruce is readily known by its leaves of one uniform dull green colour, spread equally round the branches, and by its long pendant cones. All these firs may be raised from seed, which can be separated from the cones by a moderate heat before a fire, care being taken not to destroy the vegetative power. Or the separation may be facilitated by steeping the cones a few hours in warm water. The seed ripens in December, and the cones should be preserved till April, which is the proper period for sowing. The seed must be only covered about half an inch deep. The soil should be tolerably rich. The seedlings must be transplanted the second year; for if left longer it will be completely spoiled. For the Scotch pine or fir I must refer the reader to the head Pines (Pines); and other information on the subject of firs will also be found under the head Larch. It may, however, be well to enumerate the principal other firs: anything like a description in this place would be needless.

Michaux enumerates 14 species of pines and spruces including firs, as found in different portions of the United States and Canada. His methodical arrangement of these is as follows:

Two-leaved Pines with smooth Cones.

Red (Norway) pine, or Pinus rubra. Common in Canada and the Northern Sections of the United States, but not seen in Pennsylvania south of Wilkesbarre. It is called in the state of Maine Scrub-pine. This species is found farther northward than any other pine, being seen in the environs of Hudson’s Bay. Yellow pine (Pinus nitida). This species abounds in the Middle States. In the south it is called Spruce pine, and Short-leaved pine.

Two-leaved Pines with thorny Cones.

Jersey pine (Pinus Inops). This species is not confined to the southern portion of New Jersey, but is seen in Maryland, Virginia, and others of the Southern and Western States. Table mountain pine (P. pungens). Found only on the Table mountain in North Carolina.

Three-leaved Pines with smooth Cones or very small Thorns.

Long-leaved pine (Pinus australis). This tree so extremely valuable for its timber, tar, and other resinous products, is known in the countries where it grows, and the places to which it is exported, by different names. In the Southern States, where it abounds, it is called Yellow pine, Pitch pine, and Brown pine. In England and the West Indies, Georgia pitch pine. Pitch pine (P. rigida), is found throughout the United States except the region west of the Alleghanies. It abounds on those mountains as they traverse Pennsylvania and Virginia. Lobolly Pine (P. Teda). This is common in lower Virginia and more Southern States.

Five-leaved Pines.

White pine (P. strobus). One of the most interesting of American pines. It is diffused over a great extent of country in the Northern and Eastern States, being the loftiest and most majestic production of the American forest. Its wood is most valuable for building and other purposes.

Spruces.

These have very short leaves disposed singly round the branches. The American species are, black or double spruce (A. nigra), common in the Northern States and British provinces; also in the northeastern parts of Pennsylvania, and Black Mountain of South Carolina, and sometimes in the White Cedar Swamps in New Jersey near Philadelphia and New York. In the northern seas-the spars of ships are mostly of black spruce. It is largely exported to Europe. White, or single spruce (A. alba). Common in the same northern regions of the States. Pond pine (P. serotina), common to the maritime parts of the Southern States.

Spruces with lateral Leaves.

Hemlock spruce (Abies Canadensis), natural to the coldest regions of the United States and British Provinces. It is always larger and taller than the black spruce fir. Cascades fir after fir (Abies balsamifera), or Balm of Gilead; common in the state of Maine and the British Provinces.

FISH (Lati. Piscis; Germ. Fische; Du. Vischer; Dan. and Swed. Fisk). A term used in natural history to denote every variety of animal inhabiting seas, lakes, rivers, ponds, &c. that cannot exist for any considerable time out of the water. The most natural and popular division of this subject is into fresh and saltwater fish.

According to Linnaeus, there are about 6,000 species of fish with which naturalists are acquainted, but those yet unknown are supposed to be still numerous, and many species will probably remain forever undiscovered. The anatomy and physiology of fish offer a wide field of study for the inquiring mind. Their extraordinary fecundity is truly astonishing. Fish in general are less nourishing than other animal food, but are not difficult of digestion, when in a fresh state, to a healthy stomach. To a dyspeptic stomach, however, fish is apt to prove irritating. Except in London and a few sea-port towns, the consumption of fish in England is not great. See BREEDING PONDS.

FISH, AS A MANURE. The fish which are usually employed as manures in England are sprats, pilchards, herrings, sticklebacks, and whale blubber. These are very rich fertilizers; the fleshy or muscular portions abounding in fìoil. The scales are composed of coagulated albumen and phosphate of lime; their bones are full of oil, and the solid portion is composed of phosphate of lime and carbonate of lime, in different proportions.

Sprats.—In the English counties of Essex, Kent, and Suffolk, the use of this manure is very general, although the practice is not of very long standing. The quantity applied per acre varies from 25 to 45 bushels, the poor gravelly soils requiring more than the loamy lands. They are spread by hand, from seed baskets, and on winter fallows intended for oats, on which, especially if the summer is not too dry, it produces most luxuriant crops, of a peculiar dark-green colour, yielding 10 or 11 quarters per acre, and that on land of a very second-rate description. The effect of the application, however, remains only for one crop. They produce an equally good result if mixed with earth, and suffered to remain and dissolve, for some time, in the heap, before they are carted on the land. In this way they answer exceedingly well for turnips. They
FISH.

are usually obtainable at the rate of from 6d. to 8d. per bushel.

The extent to which this manure is used may be judged by that of the Stow fishery, which is solely devoted to catching these fish. Upon this fishery the committee to whom the Houder of the Fens, at the session of 1833 reported:—

"This fishery, which prevails principally upon the Kentish, Norfolk, and Essex coasts, have been proved to your committee to occasion very extensive injury to the span and brood of fish. The nets used in it are of a very fine description, so small as not to let a pen pass through, and they enclose not only sprats, but the span and young brood of all other kinds of fish; and as these nets are frequently drawn along the ground, and in shallow waters, during the breeding season, and in the winter months before the young fish are gone into deep waters, an immense destruction of the spawn and breed of fish is the inevitable consequence; whilst, from the almost unlimited demand for this species of manure for land, and there being a ready sale for all that can be procured, this branch of fishing has greatly increased; and there are at present from 400 to 500 boats engaged in Stow-boating on the Kentish coast only, which remain upon the fishing grounds frequently for a week together, not for the purpose of catching sprats or any other fish to be sold as food in the market, but until they have obtained full cargoes of dead fish for the purpose of manuring the land."

The Farmers of Essex and Suffolk purchase these fish by thousands of bushels at a time, and carry them in wagons 10 or 15 miles into the inland districts.

Pilchards are extensively employed in Cornwall and Devonshire, both in the fresh and in the salted state. The pilchard is a small fish not larger than a herring; it visits part of the coast of Cornwall and Devon in large shoals, during the months of August and September, and again in November or December. The refuse fish, which are those principally used by the cultivator, are usually mixed with earth, sea-sand, sea-weed, or some other substance, to prevent them from causing too rapid a growth. The effects of these pilchards, according to Sir H. Davy, are apparent for several years. The pilchard is a very oily fish, and may be had in almost inexhaustible quantities. Between 8000 and 9000 persons, at sea and on shore, are employed in this fishery, and about 30,000 hogsheads are annually exported either to the West Indies or the Mediterranean.

The herring.—The employment of this valuable fish for the purpose of manuring the ground is limited to those districts near the sea to which the shoals of herring are regularly visitors; and even there, their use is confined to those seasons in which there is an annual glut, as occasionally happens on the coasts of Scotland and the eastern side of England. They are a very oily fish, and produce the same rank luxuriance of growth as sprats or pilchards. Arthur Young has given us an account of an experiment, in which some wheat, manured with these fish, grew so luxuriantly, that it was entirely laid before the period of harvest. Very numerous or accurate comparative experiments with this fish can hardly be expected, for its use must necessarily be confined to peculiar districts; and when obtained, it is generally ploughed in with considerable expedition, or dug into earth heaps, which is a mode found to answer extremely well. And it has been found, in the case of spoiled red herrings, that their application is extremely advantageous to the hop plantations. (Essay on Soil, p. 101.)

Stickles.—The use of the stickleback is principally confined to the neighbourhood of the Fens of Lincolnshire and Cambridge, in which it breeds with great rapidity, and in shallow waters they are caught at certain seasons entirely as an article for manure. They are used in much the same proportions, either by themselves or mixed with earth, &c., as sprats, and are not more durable in their good effects.

The Fat or Blubber of the Whale.—Whale blubber was employed by the late Lord Somerville, at his farm at Fairmile, in Surrey, as manure, and produced the richest crops. It was mixed with the sandy earth, and suffered to dissolve in the heap. It cost at the wharf in London 20 shillings, and, with the expenses of carriage, about 2l. per ton. It answered equally well upon arable and pasture lands, producing most luxuriant crops; and its good effects were visible for two or three years. Its general high price, however, rarely admits of its employment by the farmer.

Whale blubber is composed principally of train oil and other animal matters; but the oil is by far the largest portion of the blubber; and to the presence of this fish oil, which does not appear to differ materially in composition from whatever fish it is obtained, must be attributed the chief fertilizing value of all fish.

Train oil has been analyzed by Dr. Thomson, and found in 100 parts (Chemistry, vol. iv. p. 438),—

</tbody>
</table>

Fish oils, therefore, are composed of exactly the same materials that constitute almost all vegetable substances, differing only in the proportions; for sugar, starch, gluten, gum, &c. &c., are all composed of these three substances—carbon, hydrogen, and oxygen; blubber, therefore, may be regarded as the most condensed manure that it is possible to apply to a soil: it contains little, if any, water, and every portion of it is food for plants. The same remark will apply to the dregs of train oil, &c., which are sometimes applied, mixed with earth, to the same purpose; but it is seldom that these substances can be procured, in any quantity, at a sufficiently reasonable rate.
It is evident, from the experience of all who have tried blubber, that it is best used when previously mixed with from 10 to 20 times its weight of earth, and turned over once or twice during three or four months. It is uncombined state it is evidently too powerful. When mixed with mould, it speedily undergoes a strong fermentation, and the mass becomes of the most friable and fertilizing description. Train oil has also been employed with the most decided success; it has been used united with screened earth, and produced the most luxuriant of crops. In an experiment made by Mr. Mason, of Chilton, which is described by Lord Spenser, in a communication furnished to the Newcastle Agricultural Society, 40 gallons of unrefined train oil, which cost $3.6d. per gallon, were mixed with 120 bushels of screened earth about a month before it was applied to one acre of a tenacious soil, sown with turnips; and on an adjoining acre of similar land were applied 40 bushels of bones, broken small, and mixed with 80 bushels of burnt earth; the crop produced was as follows:—

<table>
<thead>

And in *The Mark Lane Express* of February 8, 1841, Mr. W. Sharp, of Searthing Moor, in Nottinghamshire, thus describes his experiments with fish oil, mixed with bone dust;—"I will give you my experiment with oil. The soil is a poor gravel,—the farm in the parish of Edwinstow, and enclosed off the Old Forest, near to Thorseby Park.

My attention was drawn to the use of oil in consequence of the serious expense (3l. to 4l. per acre) I was obliged to go to in bones and rape dust, for I never use yard manure for turnips, as the soil is so poor, I cannot get wheat without manure; I therefore save it all for my wheat. My first trial was in 1839, on 2 acres, in a 9-acre field, and nearly in the middle of it. I give you the cost of one acre,—

| 5 strikes of half inch bones, the dust in (2s. 7d.) | £ 1. 13. 11 |
| 2 gallons of train-oil, at 2s. 6d. per gallon | 0. 7. 6 |
| 10 strikes of coal ashes | 0. 0. 0 |

Remainder of the field as below,—

| 16 strikes of bones, as above, at 2s. 7d. per strike | £ 2. 2. 0 |
| 5 hundred of rape-dust, at 6s. 8d. per hundred | 1. 13. 9 |

With oil — 3. 15. 0

Balance in favour of oil — 2. 15. 11

"The oil turnips were as good as the remainder of the field; and all as fine as I could wish, for the land. The barley as good,—and the clover is now excellent. My next trial in 1840, on 9 acres,—

| 11 strikes of half inch bones, dust in, at 2s. 6d. per strike | £ 1. 7. 6 |
| 3 gallons of train-oil, at 2s. 6d. per gallon | 0. 7. 6 |

480

"11 acres, dressed as below, is a trial against oil,—

| 16 strikes of bones, at 2s. 6d. per strike, per acre | £ 3. 17. 6 |
| 5 hundred of rape-dust, at 6s. 8d. per hundred | 1. 13. 9 |
| 16 strikes of pigeon manure, at 1s. 6d. per strike | 1. 4. 0 |

With oil — 4. 15. 3

Balance in favour of oil — 3. 0. 2

"I think the 9 acres with oil rather the best field, and the turnips are decidedly better. The rape-dust I sow broadcast on the surface; it is then drawn in its proper place by ridging; I then drill my bones on the ridges 22 inches apart,—the turnips were white tops. I do not like the ashes mixed with the oil; it makes it dirty and bad to drill; the 11 strikes of bones carefully mixed will absorb the oil, so as to drill excellent. I let them lie about two days after mixing. I know your readers will say, how is barley grown after so light a dressing? I answer,—with my feeding sheep I use oil-cake, and with my store sheep malt-coombs, and the straw in the yard is all consumed—with oil-cake I take my seeds up for wheat.

"Some farmers may possibly doubt the correctness of my assertion, that all the principal vegetable substances are composed of precisely the same ingredients as oil and other purely animal matters; and as it is of the first importance that the cultivator should clearly understand the reason why the decomposition of animal matters furnishes such admirable food for vegetation, I must beg of him to compare the analysis of the oils which I have already stated, with that of the following common vegetable substances, as ascertained by the most careful analysis. I will merely give that of three substances:—sugar, 100 parts of which are composed, according to M. Berzelius, of—

| Oxygen | £ 51. 47 |
| Carbon | £ 41. 95 |
| Hydrogen | £ 7. 02 |

(A. Ann. of Phil. vol. v. p. 262.)

In 100 parts of starch from wheat flour are found—

| Oxygen | £ 49. 66 |
| Carbon | £ 43. 35 |
| Hydrogen | £ 6. 77 |

(Guy Lussac, Rech. vii. p. 291.)

The wood of oak is composed of—

| Oxygen | £ 41. 78 |
| Carbon | £ 50. 53 |
| Hydrogen | £ 5. 80 |

(Ibid. vol. ii. p. 294.)

"All oily and other animal substances, therefore, as they decompose in the soil, are slowly converted into those gaseous substances which are the food or breath of vegetable life, such as carbonic acid gas (fixed air) or carbonated hydrogen (the gas employed for illumination), and which are absorbed either by the roots or the leaves of the plant as they are formed. There is little or no waste in these, for when the decomposition of the oils and fibrous mat-
FISH.

ters of fish is finished, there is very little or no earthy or solid matter remaining useless in the soil. In this, again, the experience of the farmer substantiates the chemist's doctrines, for he uniformly tells us, in answer to our inquiries, that the fish only last for one crop.\th

In the east of England, the farmers of those soils conveniently situated for water carriage, employ to a very considerable extent, as manure, several kinds of fish besides sprats, such as eels, fingers, cockles, muscles, &c., and this use is only limited by the supply, or what is commonly a more important impediment, the difficulty of transporting them any distance while sufficiently fresh. When once the fish begin to putrefy, their fertilizing properties rapidly diminish; the oil from the fermenting sprats I have seen dripping from the wagons as they travelled along: thus they speedily lose in weight, and become intolerably obnoxious to the district through which they pass; several of my neighbours, indeed, take their place among my neighbours in Essex, for carrying putrefying fish through towns and populous villages.

This is hardly a matter of astonishment, since the farmer, who has to convey a freight of several hundred bushel of sprats, perhaps ten or twelve miles, has often much too little time allowed him for that purpose. The fish, perhaps, arrive stale. It is a load detained by contrary winds, or prevented by circumstances from reaching another destination? the farmer has to be informed of their arrival; he cannot despatch his teams as speedily as the nature of the case requires, the fish become offensive, and his ardour for the improvement of his land is checked by a magistrate's summons and a conviction for a nuisance. These are the reasons which retard the use of these kinds of fish as a manure, but cannot entirely prevent their being employed. Their use is still, in spite of all impediments, annually increasing, especially in the neighbourhood of those places to which the fishing smacks find a ready access. The cultivator, even of the inland soils of England, will have all these valuable sources of improvement offered for his service—fertilizers of even national interest, since they are drawn from an inexhaustible source, afford employment to a branch of industry invaluable in a maritime point of view, as a nursery for seamen, and have, moreover, this great and paramount advantage, that they add to the permanent riches of the land, and are not, as is the case with other fertilizers, drawn from one district of the state to enrich another. There need be no fear of the supply not keeping pace with the demand, for the ocean is inexhaustibly tenanted with fish. As fresh agricultural markets arise and are furnished by the railways, fresh sources of supply will be discovered, other coasts explored, and increased fisheries established. (Johnson on Fertilizers, p. 113.)

On Long Island and those parts of the New England States bordering upon the sound, or the sea, fish are very extensively and profitably used as manure. In the Chesapeake and tributaries, where herring fisheries abound, these fish are also often appropriated to the same purpose.

FISTULA (Lat.). A long sinuous ulcer, often communicating with a larger cavity, and having a small external opening.

All animals are liable to fistulas, but the horse more particularly so; they attack the withers and the poll. They are produced by blows, by bruises from the saddle, and whatever causes inflammation; also by the presence of extraneous substances.

In curing this disease, it is requisite, in the first instance, to ascertain the direction the fistula pursues, and whether it materially interferes with any of the larger blood-vessels, so as to render a full incision into the parts a matter of too much hazard to be attempted. When secure from any danger of this nature, the most effectual practice is, to lay the fistula, or fistulas, when more than one, so thoroughly open as to have a complete view of their internal surfaces. It is not, however, necessary in the simple sinus, where the matter is in a healthy state, and requires only a sufficient passage; but in cases where the discharge, by having been long detained, indurates and corrodes the contiguous parts; as the means fully adequate to remove the former avail little in the radical cure of the latter, a more severe practice of course becomes necessary.

When the fistular cavities have been fully laid open by the knife, they should be dressed with powerful caustic compositions, until the unsound parts slough away, and the wound presents a healthy appearance. Cleanliness, with more mild applications, should now be had recourse to, taking care that the wound be not closed before the cavities are properly and uniformly healed.

FIVE-FINGER. See Cinquefoil.

FIXTURES. In Law, a term generally applied to all articles of a personal nature affixed to land. This annexation must be by the article being let into, or united with the land, or with some substance previously connected therewith. Thus a barn built on a frame not let into the land, is not a fixture; a brewe's stills set in brickwork resting on a foundation, are fixtures, and the application of the same principle gives in every case the true rule to judge whether a thing be a fixture or not. Whatever is thus fixed becomes by law parcel of the freehold or realty. It is, therefore, on general principles, not removable; but there are exceptions to this rule established by custom. (Brandes's Diet. of Science.)

The English common law with regard to fixtures or any thing affixed to the freehold, is by no means so clear and defined as is desirable; and what is granted in favour of trade, to the removal of fixtures erected for the purpose of manufacture, does not extend to the creations made by tenants for agricultural purposes. The agreement made between the farmer and his landlord should therefore always contain a covenant by which this power should be clearly defined. The celebrated judgment of Lord Ellenborough in Elwes v. Mace, 3 East, 38, contains such an epitome of the law of fixtures, that I shall insert at length the opening portion of it:

"This was an action upon the case in the nature of waste by a landlord, the reversioner
in fee against his late tenant, who had held under a term for twenty-one years a farm, consisting of a messuage and lands,outhouses and barns, &c., and who at the case reserved, stated that during the term, and about fifteen years before its expiration, he erected at his own expense a beehouse, carpenter's shop, a fuel house, a cart-house, a pump-house, and a fold-yard. The buildings were of brick and mortar, and tiled, and the foundations were about a foot and a half deep in the ground. The carpenter's shop was closed in, and the other buildings were open to the court, and supported by brick pillars. The fold-yard wall was of brick and mortar, and its foundation was in the ground. The tenant previous to the expiration of his lease, pulled down the erections, dug up the foundations, and carried away the materials, leaving the premises in the same state as when he entered upon them. The case further stated these erections were necessary and convenient for the operation of the farm; and the question for the opinion of the court was whether the tenant had a right to take away those erections? Upon a full consideration, we are all of opinion that he had not a right to take away those erections."

Without any special agreement, a tenant cannot remove a border of box planted by himself; neither can ordinary tenants remove fruit trees, though planted by themselves, but nurserymen may. If the freehold is sold without any stipulation about the fixtures, they pass with the land. Neither can the fixtures be taken in execution by the sheriff. Ranges and ovens are fixtures. But a pump erected by a tenant, and so fixed as to be removable without injury to the freehold, may be taken away by him at the expiration of his term, as being an article of domestic use or convenience. A conservatory on a brick foundation, affixed to and communicating with rooms in a dwelling-house by windows and doors cannot be removed by the tenant, even if he erected them.

See Iris.

FLAG, THE SWEET. See Aromatic Reed (Calamus aromaticus).

FLAG. A term sometimes applied to the turf, or surface of the ground, which is pared off for burning. It also signifies a large flat paving stone, and the furrow-slice of ley lands, when under the plough. See Paving and Burning.

FLAIL (Lat. flagellum). A wooden implement for thrashing corn by hand. It anciently was truly a whip, and sometimes had two or more legs; the modern flail consists of the handle or staff which the labourer holds in his hand, and uses as a lever, to raise up and bring down the swipple, or part which strikes the corn, and beats out the grain and chaff from the straw. The swipple is joined to the hand-staff by the caplins or couplings, which are thongs of untanned leather, and sometimes the skins of cows or of other fish. These thongs are passed through holes in the ends of the handle and swipple, and made fast by being sewed together. The whip-flail was in use among the Romans, though the prevailing mode of separating corn from straw among the nations of antiquity was by treading it out with cattle in the open air. (See Agriculture.) In the colder parts of Europe, this could never have been generally the case, for obvious reasons; and hence the flail was the universal thrashing implement till the introduction of the thrashing machine, which is now taking the place of the flail in all countries where capitalists engage in farming. See Thrashing Machine.

FLANDERS, THE AGRICULTURE OF. The mode of tillage adopted by the cultivators of Flanders has long and beneficially engaged the attention of the British farmer; who, whatever may be his superiority to the Fleming in most respects, yet in some particular instances has learnt, and in others (such as in the careful husbanding and preparation of manure, the succession of crops, the deepening of the soil, &c.,) may still profitably imitate the practices of the small industrious cultivators of Flanders. The best report of the modern agriculture of the Flemish farmers is that drawn up for the Society for the Diffusion of Useful Knowledge, by the Rev. W. Rham, from which, and from his paper in the Journ. of Roy. Agr. Soc. of Eng. vol. ii. the chief facts of this article are obtained. The climate of Flanders pretty closely resembles that of Kent and Essex in England: it is, however, rather warmer in summer, and the snow lies longer in winter. The soil is various; there are extensive districts of sand which are brought into cultivation by dressing them with mud. In proportion to the quantity of the mud, which is a very fine clay, a portion of decayed shells and organic matter, the soil is more or less fertile; and when the mud enters into it in considerable proportion, it forms a rich compact loam. In many places there are alternate narrow strata of sand and loam, which, being mixed together, form a very productive soil. A small portion of carbonate of lime produced from the decomposition of sea shells, is found in the mud when it is analyzed; but there is no chalk, nor marl, in any portion of this soil.

The industry of the tenants of these sands is proverbial. The poor sandy heaths which have been converted into productive farms, evince their indefatigable industry and perseverance. The sand in the Campine can be compared to nothing but the sands on the seashore, which they probably were originally. It is highly interesting to follow step by step, the progress of improvement. Here you see a cottage and rude cow-shed, erected on a spot of the most unpromising aspect. The loose white sand, blown into irregular mounds, is merely swept together by the roots of the heath; a small spot only is levelled, and surrounded by a ditch. Part of this is covered with young broom; another part is covered with potatoes; and perhaps a small patch of diminutive clover may show itself; but there is a heap of dung and compost forming. The urine of the cow is collected in a small tank, or, perhaps in a cask sunk in the earth; and this is the nucleus from which, in a few years, a little farm will spread around.

Of their use of liquid manure, I shall hereafter, under that head, have occasion to speak. Their implements of husbandry are much inferior
FLANDERS.

They employ, however, the spade to a much greater extent than is done in England; and it is a common practice with them to deepen the trenches between the lands with the spade, and spread the earth over the surface of the ground: by this means the land is gradually completely trenched, and the immediate good effect by keeping the soil of the field dry is very considerable.

In a stiff loam near Alost, the following rotation is adopted: 1. Potatoes, with 20 tons of dung per acre; 2. Wheat, with 3½ tons and 50 barrels of urine; 3. Flax, with 12 tons of dung, 50 barrels of urine, and 5 cwt. of rape-cake; 4. Clover, with 20 bushels of wood-ashes; 5. Rye, with 8 tons of dung, and 50 barrels of urine. 6. Oats, with 50 barrels of urine. 7. Buckwheat without manure.

They grow large quantities of hemp and tobacco; and are large exporters of seeds of all kinds. With such exhausting crops, therefore, an attention to the careful saving of all kinds of manure is absolutely essential to the preservation of the fertility of the soil; and no cultivators are more particular in this respect than those of Flanders.

They keep large quantities of cattle. "A beast for every three acres of land is a common proportion; and in very small occupations, where much spade husbandry is used, the proportion is still greater. These are maintained on turnips, potatoes, carrots, &c., which are chopped together in a tub, with beans, rye, or buckwheat meal, and mixed with boiling water (which they call brassia), about two pails full are given each cow.

"The horses of Flanders have been long noted for their bulk. Flanders mares were at one time in request for the heavy town carriages of the nobility and men of fortune in England and on the continent. Since the improvement in the roads, and in the paving of streets, activity has been preferred to strength, and the English carriage horses now partake more of the breed of hunters, and are more nearly allied to full blood. The Flanders horses are probably the same at this time as they were a century ago; but compared with the present breeds of coach and cart-horses in England they are inferior. They are in general large in the carcass, and pretty clean in the leg; patient and enduring, if not too much hurried. They are steady in the collar, and good at a dead pull, in consequence of their weight; but they are very heavy in the forehand, inclined to get fat, and deficient in activity. They fall off in the rump, and the hips stand out too much from the ribs. The worst point in most of them is the setting on of the tail, which is low, and pointing downwards. These are the general characters of the real Flemish horse. A more useful kind of horse, although not so sleek, is found in the provinces of Brabant and Namur, where they draw heavy loads of stones and coal over bad roads. The feet of the Flemish horses are generally flat, denoting that they are well bred, and that they are fed when young, or the dung of the stables in which they have stood: for many of them have never been turned out loose, and have been reared and fed in the stable as the cows are. This will account for the want of vigour and muscle, as well as for the propensity to get fat. The food of the farmer's horses is not calculated to produce hard flesh; green clover in summer, and roots with cut straw in winter, are the chief provender."

Of the spade-husbandry of Flanders, the following description is given by the author whom I have already quoted so freely:

"The husbandry of the whole of the north-eastern part of East Flanders, where the soil is a good sandy loam, may be considered as a mixed cultivation, partly by the plough, and partly by the spade. Without the spade, it would be impossible to give that finish to the land, after it is sown, which makes it appear so like a garden, and which is the chief cause of the more certain vegetation of the seed. There is great saving of seed by this practice, as may be seen from comparing the quantity usually sown in Flanders with that which is required in other countries, where the spade is more sparingly used. In large farms in England, the spade is only used to dig out water-furrows, and to turn heaps of earth, which are made into composts with different kinds of manure. But in Flanders, where the land is usually laid in stitches of about six or seven feet wide, the intervals are always dug out with the spade, and the earth spread evenly (sifted, as they call it) over the seed which has been harrowed in. The earth may not be of a fertile nature below the immediate surface; sometimes it is only a poor sand, or a hard till; but this is no reason why it should not be dug out. If it is very light and poor, a good soaking with urine, a few days before it is dug out, will impart sufficient fertility to it. If it is very stiff, the clods must be broken as small as possible in the digging, as is done when stiff ground is trenched in gardens; and what is left unbroken on the surface, and not pulverized by passing the traimeau (a kind of heavy broad wooden sledge, made of beams of wood and boards) over it, will inevitably be reduced to a powder by the frost in winter. Thus the land is not only perfectly drained, but the seed, being covered by an inch or more of earth, is placed out of the reach of birds, without danger of being buried too deep. The soil from the bottom of the trench contains few seeds of weeds, and the root-weeds are necessarily cleaned out in the spreading. This earth, spread over the surface of the land, keeps it clean, by burying the smaller seeds, which the harrows may have brought to the surface, and preventing their vegetating. It is for this reason that the roller, or the traiomeau, is made to press the surface, or that, in very light soils, men and women tread it regularly with their feet, as gardeners do after they have sown their beds. The trench, which is thus dug, is a foot wide, or, more properly, one-sixth part of the width of the stitch, or bed; and the depth is from a foot to 18
inches, according to the soil. Thus, a layer of earth, about two inches deep, at least, is thrown over the seed, which has been sown on a surface made even by the small harrows, or the bush-harrow. These two inches gradually incorporate with the soil below; and thus, at every such operation, the soil is deepened so much.

The trenches are so arranged, that every year a fresh portion of the ground is dug out, and in six years the whole land will have been dug to the depth of at least one foot. In the next course, the trench is dug a few inches deeper, which brings up a little of the subsoil; and, after four or five such courses of trenching, the whole soil comes to be of a uniform quality to the depth of 18 or 20 inches; a most important circumstance to the growth of flax, potatoes, and carrots, all of which are very profitable crops to the farmer, and the last two indispensable to the maintenance of the labourers and the cattle. In the Waes country, they proceed differently; for they have a soil which, by repeated trenchings, has lost its natural uniformity in quality to the required depth. There they regularly trench one-sixth part of the land every year, and plant it with potatoes, or sow carrots in it.

"From this outline of Flemish husbandry," concludes Mr. Rham, "the general principles which pervade the whole system are easily discovered. The garden has evidently been the model for the operations of the farm. The spade has originally been the chief instrument of cultivation; and when a greater extent of farms necessarily introduced the plough, the favourite spade was not entirely laid aside. A Flemish farm of 40 or 50 acres must still be looked upon as an enlarged garden; and if a comparison is instituted with the cultivation of land in England, we can only compare the Flemish husbandry, as far as tillage is concerned, with those large unclosed gardens which are found in the neighbourhood of London, where the common vegetables are raised which supply the markets; where green crops are cut early for horses and cows kept in London; and where the soil is continually enriched by the manure which is brought every time a cart returns from having carried out the produce. In these grounds, the system is similar to the Flemish—deep digging, or trenching, abundant manuring, and a rapid succession of crops." (Flemish Husbandry; Journal of Roy. Agr. Soc. of Eng. vol. ii. p. 43.)

FLAX (Lat. Linum, from the Celtic word Illin, a thread; whence the Greek linen, the Ital. and Span. lino, and Fr. lin). An extensive genus of plants, of which more than 70 species are enumerated by botanists. It belongs to the natural order Linaceae. The plants are distinguished by the tenacity of their fibres, the mucilage of their seeds, and, generally, by the beauty of their flowers.

Four species only are indigenous to England, of which the common flax (L. usitatissimum) to be next noticed, is the most important and useful. As ornamental plants, they are well worth cultivating in every collection. The greenhouse and frame kinds grow best in a mixture of loam and peats; the hardy shrubby kinds do well in any light soil. The hardy herbaceous species are well suited for ornamenting flower-borders; but the dwarf kinds do best on rock-work, or in pots, that they may be protected by a frame in frosty or very wet weather; they may be increased by divisions of the root, by cuttings, or by seeds. The annual and biennial species should be sown in the open ground in April.—1. Common flax (L. usitatissimum) is an annual, rising one to two feet high, with a smooth, slender, upright stem, branched near the top, narrow lanceolate leaves, rather glaucous, blowing in July a corymbose panicle of pale purplish-blue flowers. The tests or skin of the seed abounds with mucilage; the cotyledons with oil, easily procured by pressure. The mucilage extracted by hot water is demulcent, the oil a mild laxative. The use of linseed oil in the arts is very extensive. 2. Perennial blue flax (L. perenne). 3. Narrow-leaved pale flax (L. angustifolium). 4. Purging flax (L. catharticum). The first and fourth species are mentioned further in detail in articles which follow. The others require little notice; they are found growing in sandy or chalky soils, and are perennial, flowering in June or July.

FLAX, BASTARD TOAD. See Bastard Toad-Flax.

FLAX, COMMON (Sax. flax or flax, Ger. flachs; Dutch, vlasch). The fibre of the Linum usitatissimum, which, after undergoing the process of washing, beating, and other operations, is spun into thread, and woven into linen textures, lace, &c. The seed is also crushed for oil; and the refuse husk, after the oil is expressed, is made into oilcake for cattle. The fibres of the bark of this important plant have been applied to the manufacture of thread and cloth in this and other countries from the remotest periods. "Flax," says Professor Low, "being a native plant, is sufficiently hardy to endure the climate of this and other northern countries. It has, indeed, a wide range of temperature, being cultivated, and for the like purposes, from Egypt almost to the polar circle. The wild flax grows in corn-fields, and gravelly or chalky situations; when irrigated, it thrives most luxuriantly in deep rich mould, but particularly in untilled alluvial soils. Its roots sink very deep when it has room; and it is generally said that the roots of good flax should strike into the soil to a depth equal to half the length, at least, of the stem above ground. A porous subsoil, or one that is well drained, is therefore essential. In Flanders, flax may be considered as a staple commodity, and a great portion of the population of that country is employed in preparing large quantities for exportation; the cultivation and preparing of it, is, therefore, most perfectly understood, and the Dutch flax is always well dressed, and of the finest quality. The premiums given by the legislature of England to force the cultivation of flax have had very little effect, it being one of the most exhausting crops when allowed to ripen its seed; and its culture being found to be much less profitable than corn. The native growth of flax being quite insufficient to the demand for home consumption, &c., England has long been in the habit of import-
FLAX, COMMON.

ing a large proportion of her supplies. The principal countries from whence these are obtained are Russia, the Netherlands, Prussia, and France, with small quantities from America, Italy, New South Wales, &c. The duty in England is at present 1d. per cwt.

In Ireland, flax usually follows potatoes. In Scotland, land that has been several years in pasture, and from which one crop of grain has been taken, is preferred. In Flanders, the crops which immediately precede flax, in light soils, are barley or rye, with turnips after them the same year. All these crops are more highly manured than usual, and before the flax-seed is sown, peat ashes, at the rate of 30 bushels per acre, are spread and harrowed in, and a few days afterwards 10 hogsheads of strong liquid manure is poured regularly over the land, and left for a week or 10 days to soak thoroughly into the soil. The seed is then sown very abundantly; cloudy or showery weather is the time chosen; the quantity varies, but the general proportion is 160 lbs. to the acre. It is lightly covered in by a bush-harrow, drawn over the land, for if the seed were buried more than half an inch deep it would prevent its vegetating. The choice of seed requires great care and circumspection: good fresh seed should be of a bright colour, with the hair straight, and it should be free from mud, slippery, and plump, and, on being broken, should appear of a greenish yellow colour, and should sink in water. Genuine seed will average 18 lbs. per peck, but good Riga seed is somewhat lighter. Hand weeding should be attended to when the stems are from two to three inches above the surface, for when the flax is higher, it is liable to be injured by the weeder.

The proper time for pulling flax, when not intended for seed, is when about two-thirds of the stalk is observed to turn yellow, and to lose the leaves. If intended for seed, the flax should not be pulled until the capsules have acquired a brown colour, and the points have become firm, and so sharp as to fix themselves in the hand when pressed, and when nearly all the leaves and foliage have withered and fallen from the stem.

When flax is raised both for the seed and stalk, it is submitted to an operation called rippeling, which consists in separating the seed from the stalk, by passing the flax through a kind of comb, before it is steeped in water. The iron teeth of these combs are placed so close together that the heads cannot pass through, and are consequently pulled off. Another practice is to beat out the seed in the field with a piece of wood, or a heavier stick than that of the common flail, and then to sift the seed into a large sheet. In preparing flax for the manufacturer, the first operation it undergoes is that of steeping it in water, to loosen the bark and separate it from the stalk; for this purpose it is steeped for a day, and then placed in a pond or reservoir of soft water. The sheaves are slightly covered with straw, fern, rushes, or coarse herbage (kept down by stones or heavy bodies), to prevent the flax from being discoloured by the sun. In the course of seven or eight days the rind will be sufficiently loosened, and the flax must be taken out of the water and spread out to dry. Phillips says there is an act of parliament in force, which forbids the steeping of flax in rivers, or any waters where cattle are accustomed to drink, as it is supposed to be a poison destructive to the cattle which drink of it, and to the fish which live in such waters. The odour it exhalles is most disagreeable, and has often been productive of fever. Another but far more tedious process, resorted to for separating the bark from the stalk, is called dew retting, and consists in spreading the flax upon grass lands, and exposing it to the constant action of rain and dew. Hot water and soft soap are said to decorticate the stalk in a few hours. Grassing or bleaching the flax on old grass ground is the next operation, and is intended to rectify any defect in the steeping.

The last process is that of bruising and scutching, previous to which it should be moderately dried. The woody part of the stem was formerly beaten or bruised with a hand mallet; but this operation is now more effectually performed by machinery. Flax-mills, with suitable wheels and rollers, now greatly facilitate the processes of bruising and scutching. Mr. James Durno (then British consul at Munich) gives an interesting account in the sixth volume of the Com. to Board of Agr. p. 55, of "the mode of cultivating flax and hemp in Russia, Prussia, and Poland;" and Mr. Robert Somerville of Haddington, has also a very excellent paper in the same volume (p. 84), urging very strenuously the necessity for a more general home cultivation of those essential articles, hemp and flax, and suggesting improvements in the processes of dressing, &c., many of which have since been carried out. (Brit. Annal. vol. iii. p. 42; Quart. Journ. Agr. vol. iv. p. 159; McCall's Com. Diet.)

In the United States flax, which was once considered a crop so indispensable among the crops of our farmers, is now but little cultivated; its linty product being superseded by the cotton of the South. It is a crop which involves a good deal of troublesome labour, and, without being profitable, is generally believed to be injurious to the soil; an opinion as old as the time of Virgil,—who says "Urit enim Lrvx campum seges, urit avena."—Georg. i. 71.

The seeds, besides yielding a most valuable oil, afford one of the best mucilaginous drinks for coughs, and dysenteric affections. Two or three other species are enumerated in the United States. (Flor. Cestrica.)

FLAX, PURGING. Mill mountain. Dwarf wild flax (Linum catharticum). This is a pretty herb, seldom more than eight or ten inches high, growing in the English parks, warrens, and dry hilly pastures. The stalk is slender and delicate, round, firm, and divided into small branches. The leaves are small, obuse, bright green, and standing two at each joint. The tremulous flowers are small and white, anthers blue, and the root is a small, yellow, and free from cattail. The root is small and tapering. The root is yellow and the rhizomes are white. The root is coarse and unpleasant. Chickweed. The root is small and tender. This plant is bitter and cathartic. Dr. Withering found two roots or more in a dose, of the dried herb, useful in obstinate rheumatism. It is purgative in doses of three scruples. The country people boil it in their ale or beer for

485
the cure of rheumatism; but it is not so useful as a dose of colchicum.

**FLAX-SEED.** See Linseed.

**FLAX, WILD (L. Virginianum).** A plant growing one to two feet high, often with three or four slender and angular stems from the same root, bearing pale yellow flowers of a similar kind to those found in the old fields and open woodlands of the Middle States. Authors generally describe the root of the American wild flax as annual, but Muhlenburg, Bigelow, and Darlington think it perennial. *(Flor. Cestrica).*

**FLEA (Pulex).** The flea tribe (Pulicidae) was placed among the bugs (or Hemiptera) by Fabricius. These very annoying insects are destitute of wings, have a mouth fitted for suction, and are provided with several lancet-like pieces for making punctures. They undergo a complete transformation; their larvm are worm-like and without feet; and their pupa have the legs free. The flea may almost be considered as a wingless kind of fly. Its pro-boscis seems to be intermediate in its formation between that of flies and bugs; its antennae are concealed in holes in the sides of its head, like those of certain water-bugs, which they somewhat resemble in shape; whilst the transformations of the flea are not very much unlike those of the flies, whose maggots cast off their skins on becoming pupa. *(Harris).*

Want of cleanliness contributes greatly to the multiplication of fleas, and hence the propriety of the frequent removal of straw and rubbish from about houses and yards, and recourse to sweeping of floors, especially when carpeted. Various devices are adopted for the purpose of expelling fleas. Frequent sprinkling of a room with a simple decoction of worm-wood, or sassafras, will soon extirpate the whole breed of these troublesome vermin; and the best remedy to expel them from bed-clothes, is a bag filled with dry roots, the colour of which is to them extremely offensive. Others cover the floors of the rooms where fleas abound with the leaves of the elder tree, while the dew is on the foliage, to which these insects fondly adhere, and thus may be easily destroyed. Fumigation with the leaves of pennyroyal, or the fresh gathered foliage of that plant, sewed up in a bag, and laid in the bed, are also remedies pointed out for the expulsion of fleas. Sprinkle with camphorated whisky or other ardent spirits.

Dogs and cats may be effectually secured from the persecutions of these vermin, by occasionally anointing their skin with sweet oil. The fleas and lice of poultry are destroyed by a decoction of sassafras wood. *(Domestic Economy.)*

**FLEABANE (Erigeron, from er, spring; and geron, an old man; the plants become old in the beginning of the season).** This extensive genus comprehends many exceedingly handsome species, varying from a few inches to two feet or more high, and producing a great and copious display of blossom; they will grow in almost any soil, and are increased with facility from either seeds or divisions. The fleabane has lost its reputation both for banishing fleas and insects by its smell, and answering other superstitious incantations, for which it was celebrated in former times. There are four indigenous species. The Canada fleabane (E. Canadensis), and blue fleabane (E. acris), which are diuretic. The alpine fleabane (E. alpina), and pale-rayed mountain fleabane (E. caespitosa). The first is annual, the second biennial, the third and fourth perennial.

Several species are found in the United States, among which are the *E. Canadensis,* called Horse-weed, and *E. strigosus,* called Bunache and Daisy, a very common and worthless weed in the Middle States, where it frequents the pastures, flowering in June and July, and maturing its seed in September. It is particularly injurious to the first crop of upland meadows, after a course of grain crops. *E. Philadelphicus.* *E. Pulchella,* or Handsome Erigeron. *E. Heterophyllus* or various-leaved Erigeron, together with some eight or ten additional species. See Daisy. *(Flor. Cestrica).*

**FLEABANE, COMMON (Erodula dysenterica).** This plant is very abundant in clear ditches and in watery places about road-sides. It is a perennial, with a creeping root; herb more or less woolly or corynous, glabrous, with a peculiar acid aromatic scent, somewhat like the flavour of peaches. The stem is 15 or 18 inches high, branched and leafy, corymbose at the summit, with many bright yellow flowers. Linnaeus records, on the authority of General Keith, that the use of this plant cured the Russian army of dysentery;—hence the specific name. Its medical properties, however, are simply diuretic. The small fleabane (E. pulicaria), is an annual, and is said to banish insects by its smell. It grows on moist sandy spots, especially where water has stagnated during winter. There is another species, the sabre-leafed fleabane, which grows on the seacoast, in a muddy soil. *(Eng. Flor. vol. iii. p. 440—443.)*

**FLEABANE, GREAT.** Ploughman's Spike-nard. See Spikenard.

**FLEA-BEETLE (Holitica).** Several of these have been described among the insects destructive to the cucumber. Some others known in the United States and described by Dr. Harris, will be referred to under different heads. See TUNTIE FLY, VINE BEETLE, &c.

**FLEAM.** In farriery, an instrument used for letting blood in horses or other animals.

**FLEA-WORT (Plantago).** A genus, the greater number of the species of which are mere weeds, of the easiest culture and propagation. See Plantain.

**FLECKED.** A provincial term used to signify pied, as cattle.

**FLEECE.** The woolly covering scorned from off the body of the sheep. Mr. James Dickson of Edinburgh contributed a very able prize essay to the Highland Society (Trans. vol. vi. p. 205), “on the treatment of sheep, with a view to the improvement of the fleece.” The earliest and rudest method of obtaining the fleece was to drive the flocks hastily through a narrow passage, when by their pressure against each other the greater part of the fleece
was loosened, or completely detached. To this succeeded another more inhuman mode. The sheep was caught, and the fleece pulled from its back. This barbarous practice prevailed to a very recent date in the Orkney Islands. In England the average value of the fleece in 1315 was 6d. (7s. 6d. of the present money), being nearly half as much as the value of the carcass. (The Sheep, Lib. of Use. Know. p. 33, 205.) See Hair, Sheeph-Shearing, and Wool.

FLEMISH HUSBANDRY. See Flanders, Agriculture of.

FLESH. Muscular flesh, which is too well known to need any particular description, is composed of a number of white or red meshes, cake-like in smaller fragments. It is united in ordinary cases with a variety of substances, such as blood, fat, ligament, sinew, and nerves. It has been analysed by M. Berzelius who found in it—

The chief nutriment afforded by animal food is derived from muscle or flesh. That of adult animals is more nutritive than that of young animals; hence beef and mutton are better adapted to support the frame than veal or lamb. The latter yield most gelatin; but the popular idea of the nutritive property of animal jellies is erroneous.

FLIES. “A host of flies,” says Harris, “forming nearly one-third of the whole number of species in the order Diptera, will be found to have a short and soft proboscis, ending with large fleshy lips, enclosing only two bristles, and capable of being drawn up within the cavity of the mouth. Their antennae are generally short, hang down over the face, and end with a large oval joint, bearing a little bristle. Their larvae, or young, are fleshy, whitish maggots, which never cast their skins, but when the pupa-state comes on, shorten, take the old oval form of an egg, and become brown, dry, and hard on the outside. This immense tribe includes the various kinds of flesh-flies, blow-flies, house-flies, dung-flies, flower-flies, fruit-flies, two-winged gall-flies, cheese-flies, and many others, for which we have no common names, but all composing the tribe of Muscans, or Muscidae. Some of these flies do not strictly conform to the foregoing characters of the tribe, in all respects; but the exceptions are few in number, and the most remarkable of them will be noticed in the following pages.

Many flies of this tribe are parasitic in their larve state, their young living and undergoing their transformations within the bodies of other insects, particularly in caterpillars, which they thereby destroy. These flies belong chiefly to the family of Tachinidae, a name applied to them on account of the swiftness of their flight. In form they somewhat resemble house-flies; like them they have very large winglets, and their wings spread apart when they are at rest. They are easily distinguished, however, by the stiff hairs, whereby they are more or less covered, and by the bristles on their antennae, which are not usually feathered. A large fly of this kind, the Tachina vivida of my 'Catalogue,' is often seen on fences, and on plants, and sometimes in houses, towards the end of June and during the month of July. Its large, oval hind-body is of a clear light-red colour, with two or three black spots in a row, on the top of it, and a thick row of black bristles across each ring. The face is grayish white, like satin, and the hairs are copper-coloured. The thorax is gray, with brownish lines upon it. The antenna, proboscis, and legs are light red. Its body is short and thick, and is about half an inch long, and its wings expand rather more than nine-tenths of an inch.”

Viviparous Flesh-flies. — Most insects are hatched from eggs which are laid by the mother on the substances that are to serve for the food of her young. Some flesh-flies produce their young alive, or already hatched, and drop them on the dead and putrefying animal matter, which they are obliged to consume and remove in the shortest possible time. An exception from the usual course among insects appears therefore to have been made in favour of these viviparous flesh-flies, to enable their young promptly to perform their appointed tasks. These insects produce an immense number of young, as many as 20,000 having been observed by Réaumur in a single fly. Our largest viviparous American flesh-fly is the Sarcophasa Georgiana of Wiedemann. It appears towards the end of June, and continues till the middle of August, or perhaps later. Its face is silvery white, and there is an oblong square black spot between the eyes, which are copper-coloured. The thorax is light gray, with seven black stripes upon it. The hind-body is nearly conical, has the lustre of satin, and is checkerred with square spots of black and white, shifting or interchanging their colours according to the light wherein they are seen. The legs are black, and the hindmost pair are very hairy in the males. The female is about half an inch long; and the male is rather smaller. In the Sarco- phagans, or flesh-eaters, as the name implies, the bristles on the antennae are feathered.

Stable-fly. — “The flies that abound in American stables in August and September, and sometimes enter houses on the approach of rain, might be mistaken for house-flies, were it not for the severity of their bites, which are often felt through our clothing, and are generally followed by blood. Upon examination they will be found to differ essentially from house-flies in their proboscis, which is very long and slender, and projects horizontally beyond the head. The bristles on their antennae are feathered above. Cattle suffer sorely from the piercing bites of these flies, and horses are sometimes so much tormented and enraged by them as to become entirely ungovernable in harness. The name of this kind of fly is Stomoxys calcitrans; the first word signifying sharp-mouthed, and the second kicking, given to the fly from the effect it produces on horses. It lays its eggs in

487
dung, where its young are hatched, and pass through their transformations. The larvæ and pupæ do not differ much in appearance from those of common house-flies.

**Meat-flies.**—"It is found all summer about slaughter-houses, butchers' stalls, and pantries, which it frequents for the purpose of laying its eggs on meat. The eggs are commonly called fly-blows; they hatch in two or three hours after they are laid, and the maggots produced from them come to their growth in three or four days, after which they creep away into some dark crevice, or burrow in the ground, if they can get at it, turn to egg-shaped pupæ, and come out as flies, in a few days more; or they remain unchanged through the winter, if they have been hatched late in the summer. A smaller fly, of a brilliant blue-green colour, with black legs, also lays its eggs on meat, but more often on dead animals in the fields. It seems hardly to differ from the *Musca (Lucilia) Cæsar of Europe.* The house-fly of this country has been supposed to be the same as the European *Musca domestica.* I cannot satisfy myself on this point for the want of specimens from Europe. It is possible that our sharp-biting stable-flies, the meat-flies, and the house-fly, may really be distinct species from those which are found in Europe."

**House-fly.**—The American house-fly is the *Musca avara,* or harpy-fly of Dr. Harris's Catalogue. It begins to appear in houses in July, becomes exceedingly abundant in September, and does not disappear till killed by cold weather. It is probable that, like the domestic fly of Europe, it lays its eggs in dung, in which its larvae live, and pass through their changes of form. The Americans are accused of carelessness in regard to flies, and apparently with some reason. But, if these filthy, dung-bred creatures swarm in some houses, covering every article of food by day, and absolutely blackening the walls by night, in others comparatively few are found; for the tidy house-keeper takes care not to leave food of any kind standing about, uncovered, to entice them in, and makes a business of the rink or the intruders at least once a day. If a plateful of strong green tea, well sweetened, be placed in an outer apartment accessible to flies, they will taste of it, and be killed thereby, as surely as by the most approved fly-poison. In the first volume of *The Transactions of the Entomological Society of London,* Mr. Spence gives an account of a mode of excluding flies from apartments, which has been tried with complete success in England. It consists of netting, made of fine worsted or thread, in large meshes, but half of an inch or more apart, stretched across the windows. It appears that the flies will not attempt to pass through the meshes, or between the threads, into a room which is lighted only on one side; but if there are windows on another side of the room, they will then fly through; such windows should therefore be darkened with shutters or thick curtains.

(Harris.)

**FLINT.** Common flints are nearly pure silice, which is composed of a neutral (silicic) acid, and oxygen gas; it is tasteless, insoluble in water, or fluoric acid, and dissolvable only by means of potash. Flints usually occur in irregular nodules in chalk. They abound considerably in some sorts of soils. Sand is commonly chiefly composed of flint. A specimen of flint analyzed by M. Klaproth contained

Flint, when exposed to intense heat, becomes opaque, and forms a kind of porcelain. This was well illustrated in the fire in the Tower of London, in 1841. The flints of the muskets were all thus changed. See EARTH.

**FLOAT.** A raft of timber bound together to be conveyed by water. It also signifies locally to turn water upon meadow land for improving it; and likewise to pare off the surface or sward.

**FLOATING OF MEADOWS.** See IRRIGATION.

**FLOUR.** (Span. flor: It. fiore: Fr. fleur de farine). The meal of wheat corn or other grain, separated from the husk or bran, and finally ground and sifted. There are in England three qualities of flour, denominated first, seconds, and thirds, of which the first is the purest. (See BREAD.) The proportion of flour which a bushel of grain affords greatly varies. A bushel of Essex wheat, Winchester measure, weighs upon an average about 60 lbs., which, when ground, will yield (exclusive of the loss incurred by the grinding and drying) 454 lbs. of the flour called *seconds,* which alone is used for baking throughout the greater part of England, and affords the most wholesome, though not the whitest bread. Besides the seconds, such a bushel of wheat yields 13 lbs. of pollard and bran; the total loss in grinding seldom exceeds one pound and a half.

The corn of the different species of grain produces, when ripe, nearly the following quantities of meal or household flour and bread per bushel: viz.

The flour of wheat which is cut before it is quite ripe is whiter than that which is allowed to come to maturity, and bears a higher price in the markets. The grain which is intended for the miller should, therefore, be reaped before it has reached its utmost growth; but that which is meant for seed should be allowed to ripen until the last moment at which it can be cut with safety. The corn is ground into meal of various degrees of fineness, and a bushel of 60 lbs. generally yields, when dressed, about the following quantities, viz.

A bushel of wheat, therefore, averages 48 lbs. of both kinds of flour of the sort called "seconds," and a sack of marketable flour should by law weigh 280 lbs. These products must,
FLOWER DE LUCE.

however, vary according to the quality of the grain; some will produce more or less bran, as the husk may be more or less thick; and the bakers admit they can make two or three more quarters of flour from one sack of flour, when it is the genuine produce of good wheat. Thus it was found upon a comparative trial between English and Scotch wheat, of apparently equal quality, that there was a difference in favour of the former of no less than 13 lbs. of bread made 2½ cwt. of flour. (Willich's Dom. Encyc.; Brit. Husb. vol. ii. pp. 137, 155.)

FLOWER DE LUCE, or LIS. FLAG. See Iris.

FLOWERING ASH (Scopolia). All the species of the genus scopolia are ornamental and useful; they are easily cultivated, and may be raised from seeds, like the common ash, or they may be increased by budding or grafting on the common ash.

FLOWERING RUSH, COMMON (Butomus umbellatus). This beautiful aquatic plant is in England a native of ponds, ditches, and the margins of rivers on a gravelly soil. It flowers in July and August. The leaves are narrow, acute, nearly a yard long. The stalk is still taller, round, and very smooth, and bears a large fructified umbel of handsome rose-coloured flowers, each about an inch broad, without scent. This rush may be increased with little difficulty. The leaves of this plant are said to cause the mouths of cattle to bleat that crop it; hence the name, from bous, ox, and feanno, to cut. It was some years since much celebrated in Russia as a remedy for hydrophobia; but like all specifics, its fame was destroyed by excess of praise. It has no influence in curing that disease.

FLOWERS. The most beautiful parts of plants and trees, which contain the organs of fruitication. (See Botany.) From their frequent utility as medicinal drugs, as well as their external beauty, the cultivation of flowers in our gardens becomes an object of some importance. Flowers are many of them excellent indicators of the approaching weather by expansion or closing, and other motions. It is an established fact, that flowers as well as fruits grow larger in the shade, and ripen and decay sooner when exposed to the sun. The immediate cause of the various colours presented by some flowers, such as poppies, has not hitherto been distinctly ascertained. Colouring matter is contained in almost every flower and root of vegetables, and may be extracted by a very simple process. Flowers which are to be used or preserved for medicinal purposes should, with a few exceptions, be gathered in full bloom, and dried as speedily as possible. The rose, Rosa Gallica, is gathered before it is fully blown. In drying flowers, the calyces, claws, &c., should be precisely taken off: when the flowers are very small, the calyx is left, or even the whole flowering spike, as in the greatest portion of the labiate flowers. In some instances, as in the bauiatines, or pomegranate flower, the active matter resides chiefly in the calyx. Compound flowers with pappose seeds, as cotis's-foot, ought to be dried very high, and before they are entirely open, otherwise the slight moisture that remains would develope the pappus, and form a kind of cottony nap, which would be very hurtful in infusions, by leaving irritating particles in the throat. Flowers of little or no smell may be dried in a heat of 75 to 100° Fahr. The succulent petals of the lilaceous plants, whose odour is very fugacious, cannot well be dried, as their mucilaginous substance rots and grows black. Several sorts of flowering tops, as those of lesser centaury, wormwood, melilot, water germander, &c., are tied in small parcels and hung up, or else exposed to the sun, wrapped in paper cornets, that they may not be discoloured. After some time, blue flowers, as those of violets, bugloss, or borage, grow yellow, and even become entirely discoloured, especially if they are kept in glass vessels that admit the light: if however, they are dipped for a moment in boiling water, and slightly pressed before they are put into the drying stove, the blue colour is rendered permanent. (Gray's Sup. to Pharmacop.) It is probable that varieties in the colours of single flowers raised from seeds may be generally obtained by sowing those which already possess different shades contigious to others of the same species; or by bending the flowers of one colour, and shaking the anther-dust over those of another. The origin of double flowers is believed to result from the luxuriant growth of the plant, in consequence of excessive nourishment, moisture, and warmth; they arise from the increase of some parts of the flower, and the consequent exclusion of others: thus the stamens are often converted into petals. Botanists very properly term such multiplied flowers vegetable monsters, because they possess no stamens or pistils, and therefore cannot produce seeds. There subsists (says Dr. Darwin) a curious analogy between these vegetable monsters and those of the animal world; for a duplication of limbs frequently attend the latter, as chickens and turkeys with four legs and four wings, and calves with two heads, &c. The science of floriculture, or the culture, propagation, and general management of plants, divides itself into five sections, viz. 1. Stove plants; 2. Greenhouse plants; 3. Hardy trees and shrubs; 4. Hardy herbaceous plants; 5. Annuals and biennials.

FLUKE WORM (Distoma hepaticum; Fasciola hepatica, Linn.). A small flat cestosworm or worm, about an inch long, which infests the duets of the liver and gall-bladder of different animals, especially sheep. In those that have died of the rod, it is generally found fixed by two points, one at one extremity, and the other about the middle of the abdomen of the worm; it bears some resemblance to the seed of the common gourd, and thence is often called the gourd-worm. See Sheep, Diseases of. FLY IN SHEEP. FLY IN SHEEP, DISEASES OF.

FLY IN TURNIPS (Alitica nemorum). A species of flea-beetle, which in England attacks the turnip crop in the cotyledon, or seed leaf, as soon as it appears; it is sometimes called the black jack, and sometimes the fleas, or black fly. All the species are among the smallest insects; several are scarcely a line

62
FLY IN TURNIPS.

Mr. Duncan, and in the order Coleoptera, from its wings with which it flies being folded beneath two horn cases. It is included in the family Chrysomelidae, or golden beetles, for certain conformity with its structure, and is one of about 100 species forming the genus Altica, sometimes written Haloica. The striped turnip beetle is named in the English catalogues Altica nemorum. The former word, derived from the Greek, alludes to the leaping powers of the genus, and the latter signifying that this species inhabits woods and groves, which were more especially its haunts before turnip cultivation became general. See Cucumber Insects.

The remedies recommended are numerous, amongst which hoeing and rolling may harass and kill many of the beetles; and as this process promotes the more rapid growth of the plants, it must be attended with no slight advantages. From the dislike the fly has to repeated wet, frequent watering the turnips would evidently be very beneficial, particularly with brine (not strong enough to injure the plants) or liquid manure, which would stimulate the growth most effectually; and many of the beetles would necessarily be forcibly brushed off, and get set among the earth, and be thus dusted and sprinkled by machinery would also have a powerful effect. Nitrate of soda has been tried in a few instances on crops of Swedish turnips with very beneficial results. A net (called after its inventor the Paul net) dragged over the field has been usefully employed; and a board newly painted with white paint, or tarred, drawn over the turnips, will catch multitudes of the beetles; for, on being disturbed, they leap against it, and cannot readily escape themselves.

The rapid growth of the plant appears to be the best security against the ravages of the insect; and to insure this, plenty of seed should be sown, all of the same year's growth. Deep ploughing will be found advantageous when the chrysalides are in the soil. Drilling is far superior to broadcast sowing, and in Scotland is believed to keep away the beetles. Early sowing is attended with disadvantages; for the same warmth and sunshine that make the seed vegetate will also bring the hungry swarms of beetles from their winter quarters.

In England, where the ravages of the flea-beetle have attracted so much attention, it is thought that the careful and systematic use of lime will obviate, in a great degree, the danger which has been experienced from this insect. As soon as the plants appear above ground they are to be dusted with quicklime, and this is to be repeated as often as rain or wind blows it off and the fly reappears. Watering plants with alkaline solutions, it is said, will kill the insects without injuring the plants. To make the solution, 1 lb. of hard soap may be dissolved in 12 gallons of soap-suds left after washing clothes. This may be sprinkled twice a day by means of a watering pot. The solution of whale oil soap as recommended for the destruction of Aphides or plant-lice, would doubtless answer an excellent purpose in destroying the turnip fly.

The turnip saw-fly (Athalia spinarum), is a less common depredator, but in England is occasionally found in company with the former. A very minute account of it is given by Mr. Shibree. It is named after the destruction of plants (not ground plants) which it has been known to do. It receives its name from the use and appearance of the instrument with which it deposits its eggs. This is placed at the extremity of the abdomen of the female, on the under side, and is so constructed that it combines the properties of a saw and auger. (Kollar on Insects injurious to Farmers, Miss Loudon's Travels; Dowcaster Report; Mr. Curtis on Insects affecting the Turnip Crop; Prout. Husbandry; Harris on Depluctive Insects.)

FLY IN WHEAT (Tityps tritici, Kirby; Cecidomyia tritici, Latr.). See Pl. 2, i. In England when the wheat is in blossom, it is sometimes attacked by this small beautiful fly, with an orange-coloured body and white wings, which lays its eggs in the middle of the blossom, by means of a long retractile ovipositor. When the eggs are hatched, the larvae, which are very small, from 10 to 14 being sometimes found in one grain, prevent the fruiting of the grains, probably by eating the pollen, and thus frequently destroy some part of the harvest. Mr. Shirreff, in vol. iii. p. 558, says that the fly generally appears when the wheat plant comes into ear. In 1829 and 1830, flies were first seen by him on the 21st of June, and, in 1831, on the 10th of the same month. The larvae, after a period, fall to the ground, and burrow in the earth, where they remain till the following summer. According to Mr. Gorrie (Mag. Nat. Hist., Sept., 1829, p. 324), all the larvae have quitted the ears of wheat and descended to the earth by the 1st of August; going into the ground to about the depth of half an inch, where it is probable that they pass the winter in the pupa state. The extraordinary smallness of this insect, both in its larva and perfect state, with the circumstance that the destruction of the wheat takes place when it is in blossom, and that not all the ears on one and the same field are attacked, allows of but little that can be effected by human aid against this enemy of grain. The safest and almost only certain means of diminishing such an evil for the succeeding year, consists in not sowing wheat again on the same field, nor in its neighbourhood; for, in all probability, the pupa lie in the earth, and will
FLY IN WHEAT.

Only become flies next year at the season when the corn is in blossom. Fortunately, nature as in this case provided another still smaller parasitic insect, allied to the family of Ichneumons, to keep the midge also within its proper bounds. Mr. Kirby, who first made us acquainted with the natural history of this insect, calls the parasite Ichneumon Tipule. It is a species of the genus Platystygaster of Latreille, belonging to the family Proctotrupidae.

Mr. Gorrie states that, from the experiments which he made in the season 1831, the variety of wheat cultivated under the name of Cone (Triticium, Pl. 2, d), is not liable to the attacks of the fly. (Quart. Journ. of Agr. vol. iii. p. 639.) Mr. Shirreff (Ibid. p. 305), also considers the Polish wheat (T. Polonicum, Pl. 2, b), to be in a measure secure from its attacks.

The ravages caused by the wheat-fly in Scotland are sometimes very extensive. It is stated by Mr. Shirreff, that throughout the whole of East Lothian, during the years 1827, 1828, 1829, and 1830, the fly injured the wheat crop to the amount of 30 per cent. Should the fly be found in this proportion throughout the kingdom in successive years, the loss to the community would be incalculable. Mr. Gorrie seems to think that the wheat-fly maggots might be so buried as not to be able to work their way up through the superincumbent soil; if, in a ploughing in the wheat stubble, a scarehouse skimmer were fixed upon the beam before the coulter, so constructed as to lay about an inch of the surface in the bottom of the furrow. There is another kind of fly or midge (Tipula reata, Sauter), which is particularly injurious to spelt (a kind of dwarf wheat) and barley. (Kollar on Insects injurious to Agriculture. Quart. Journ. of Agr. vol. ii. p. 3: Wetwood on Wheat Flies, in Gard. Mag. vol. xiii. p. 289.)

An insect resembling the European wheat-fly in its habits, and known, in its maggot form, by the name of the "gran-worm," has been observed for several years in the northern and eastern parts of the United States and in Canada. (See Pl. 2, i, where the maggot and fly are represented as highly magnified.) "It seems," says Dr. Harris, "to have been mistaken by some for the grain-weevil, the Angoumois grain-moth, and the Hessian fly, and its history has been so confounded with that of another insect, also called the grain-worm in some parts of the country, that it is difficult to ascertain the amount of injury done by either of them alone. The wheat-fly is said to have been first seen in America about the year 1828, in the northern part of Vermont, and on the orders of Lower Canada. From these places its ravages have gradually extended in various directions from year to year. A considerable part of Upper Canada, of New York, New Hampshire, and of Massachusetts has been infested by it; and, in 1834, it appeared in Maine, which it has traversed, in an easterly course, at the rate of 20 or 30 miles a year.

The country over which it has spread has continued to suffer more or less from its alarming depredations, the loss which has been found to vary from about one-tenth part to nearly the whole of the annual crop of wheat; nor has the insect entirely disappeared in any place till it has been starved out by a change of agriculture, or by the substitution of late-sown spring wheat for the other various sorts of grain. Many communications on this destructive insect have appeared in the Genera Farmer and in the Cultivator, some of them written by the late Judge Buel, by whom, as well as by the editors of the Yankee Farmer, rewards were offered for the discovery of the means to prevent its ravages. Premiums have also been proposed for the same end by the Kennebec County Agricultural Society, in Maine, which were followed by the publication in the Maine Farmer of three "Essays on the "Gran-Worm," presented to that Society. These essays were reprinted in the 17th volume of the New England Farmer, wherein, as well as in some other volumes of the same work, several other articles on this insect may be found.

The American wheat-insect, in its winged form, has not yet fallen under my notice. It is stated by Judge Buel, Mrs. Gage, and others, to agree exactly with the description of the European wheat-fly (Cecidomyia tritici), being a very small, orange-coloured gnat, with long, slender legs, and two transparent wings, which reflect the light of the rainbow. Immense swarms of these orange-coloured gnats infest fields of grain towards the last of June. While the sun shines they conceal themselves among the leaves and weeds near the ground. They take wing during the morning and evening twilight, and also in cloudy weather, when they lay their eggs in the opening flowers of the grain. New swarms continue to come forth in succession, till the end of July; but Mr. Buel says that the principal deposit of eggs is made in the first half of July, when late sown winter-wheat and early sown spring-wheat are in the blossom or milk. The flies are not confined to wheat alone, but deposit in barley, rye, and oats, when these plants are in flower at the time of their appearance. The eggs hatch in about eight days after they are laid, when the little yellow maggots or grain-worms may be found within the chaffy scales of the grain. Being hatched at various times during a period of four or five weeks, they do not all arrive at maturity together. Mrs. Gage informs me that they appear to come to their growth in 12 or 14 days. Specimens of these maggots which she has sent to me were found to agree, in every respect, with the descriptions and figures of those of the European wheat-fly. They do not exceed one-eighth of an inch in length, and are not provided with feet. From 2 to 15 or 20 have been found within the husk of a single grain, and sometimes in every husk in the ear. After a shower of rain they have been seen in such countless numbers on the beards of the wheat, as to give a yellow colour to the whole field. These insects prey on the grain in the milky state, and their ravages cease when the grain becomes hard. They do not develop within the kernels, but live on the pollen and on the soft matter of the grain, which they probably extract from the base of the germs. It appears, from various statements, that very early and very late wheat escape with comparatively little injury; the amount of which, in other cases, depends upon the condition of the
FLY IN WHEAT.

When the maggots begin their depredations soon after the blossoming of the grain, they do the greatest injury, for the kernels never fill out at all. Pinched or partly filled kernels are the consequence of their attacks when the grain is more advanced. The hulls of the impoverished kernels will always be found split open on the convex side, so as to expose the embryo. This is caused by the drying and shrinking of the hull, after a portion of the contents thereof has been sucked out by the maggots. Towards the end of July and in the beginning of August the full-grown maggots leave off eating, and pass sloughs of the embryo, which process, which has been alluded to by Judge Buel and other writers, has been carefully observed by Mrs. Gage, who has sent to me the maggots before and after moulting, together with some of their cast skins. Within two or three days after moulting, the maggots either drop of their own accord, or are shaken out of the ears by the wind, and fall to the ground. They do not let themselves down by threads, for they are not able to spin. Nearly all of them disappear before the middle of August, and are very rarely found in the grain at the time of harvest.

"Several cases of the efficacy of fumigation in preventing the depredations of these insects are recorded in our agricultural papers. For this purpose brimstone has been used, in the proportion of one pound to every bushel of seed sown. Strips of woolen cloth, dipped in melted brimstone, and fastened to sticks in different parts of the field, and particularly on the windward side, are set on fire, for several evenings in succession, at the time when the grain is in blossom; the smoke and fumes thus penetrate the standing grain, and prove very offensive or destructive to the flies, which are laying their eggs. A thick smoke from heaps of burning weeds, sprinkled with brimstone, around the sides of the field, has also been recommended. Lime or ashes, strown over the grain when in blossom, has, in some cases, appeared to protect the crop; and the Rev. Henry Colman, the Commissioner for the Agricultural Survey of Massachusetts, says that these are very preventive, if not infallible, may be relied on with strong confidence. For every acre of grain, from one peck to a bushel of newly slaked lime or of good wood ashes will be required; and this should be scattered over the plants when they are wet with dew or rain. Two or three applications of it have sometimes been found necessary. Whether it be possible to destroy the maggots after they have left the grain, and have betaken themselves to their winter quarters, just below the surface of the ground, remains to be proved. Some persons have advised burning the stubble, and ploughing up the ground, soon after the grain is harvested, in order to kill the maggots, or to bury them so deeply that they could not make their escape after they were transformed to flies. Perhaps thoroughly liming the soil before it is ploughed may contribute to the destruction of the insects. It is stated that our crops may be saved from injury by sowing early in the autumn or late in the spring. By the first, it is supposed that the grain will become hard before many of the flies make their appearance; and by the latter, the plants do not come into blossom until the flies have disappeared. In those parts of New England where these insects have done the greatest injury, the cultivation of fall-sown or winter grain has been given up; and this, for some years to come, will be found the safest course. The proper time for sowing in the spring will vary with the latitude and elevation of the place, and the forwardness of the season. From numerous observations made in this part of the country, it appears that grain sown after the 16th or 19th of May generally escapes the ravages of these destructive insects. Late sowing has almost entirely banished the wheat-flies from those parts of Vermont where they first appeared; and there is good reason to expect that these depredators will be completely starved out and exterminated, when the means above recommended have been generally adopted and persevered in for several years in succession.

"Mrs. Gage has discovered another pernicious insect in the ears of growing wheat. It seems more distinct from the wheat-fly than the span-worm, and is situated in Europe to a great extent. This insect belongs to the order Hemiptera. In its larva state it is smaller than the wheat-maggot, is orange-coloured, and is provided with six legs, two antennae, and a short beak, and is very nimble in its motions. It is supposed to suck out the juices of the seed, thus causing the latter to shrink, and become what the English farmers call pungled. This little pest may probably be destroyed by giving the grain a thorough coating of slaked lime.

"Our agricultural papers contain some accounts of an insect or insects much larger than the maggots of the wheat-fly, growing to the length of three-eighths of an inch or more, and devouring the grain in the ear, and after it is harvested. The insects to which I allude have received the names of wheat-worms, gray worms, and brown weevils; and, although these different names may possibly refer to two or more distinct species, I am inclined to think that all of them are intended for only one kind of insect. Sometimes this has also been called the grain-worm; whereby it becomes somewhat difficult to separate the accounts of its history and depredations from those of the Cidionogia, or wheat-insect, described in the foregoing pages. It may, however, very safely be asserted that the wheat-worm of the western part of New York and of the northern part of Pennsylvania is entirely distinct from the maggots of our wheat-fly, and that it does not belong to the same order of insects. From the description of it, published in the sixth volume of the Cultivator, by Mr. Willis Gaylord, this depredator appears to be a caterpillar, or span-worm, being provided with twelve feet, six of which are situated near each extremity of its body. Like other span-worms, or Geometers, it has the power of spinning and suspending itself by a thread. Mr. Gaylord says that it is of a yellowish-brown or butternut colour; that it not only feeds on the kernel in
FLY IN WHEAT.

The milky state, but also devours the germinating end of the ripened grain, without, however, burying itself within the hull; and that it is found in great numbers, in the chaff, when the grain is threshed. He says, moreover, that it has been known for years in the western part of New York; and that it is not so much the new appearance of this insect, as its increase, which has caused the present alarm respecting it. The transformations and the appearance of this insect in its perfected state have not yet been described. Mr. Nathaniel Sill, of Warren, N.H., has given somewhat different description of it. On threshing his winter-wheat, immediately after harvest, he found among the screenings a vast army of this new enemy. He says that it was a caterpillar, about three-eighths of an inch in length, when fully grown, and apparently of a straw-colour; but, when seen through a magnifier, was found to be striped lengthwise with orange and cream colour. Its head was dark brown. It was provided with legs, could suspend itself by a thread, and resembled a caterpillar in all its motions. This insect ought not to be confounded with the smaller worms found by Mr. Sill in the upper joints of the stems of the wheat, and within the kernels, until their identity has been proved by further observations. It appears highly probable that Mr. Gaylord's and Mr. Sill's wheat-caterpillars are the same, notwithstanding the difference in their colour. Insects, of the same size as these caterpillars, and of a brownish colour, have been found in various parts of Maine, where they have done much injury to the grain. Unlike the maggots of the wheat-fly, with which they have been confounded, they remain depredating upon the ears of the grain until after the time of harvest. Immense numbers of them have been seen upon barn-floors, where the grain has been threshed, but they soon crawl away, and conceal themselves in crevices, where they probably undergo their transformations. These wheat-worms, or wheat-caterpillars, as they ought to be called, if the foregoing accounts really refer to the same kind of insect, are supposed by some persons to be identical with the clover-worms, which have been found in clover, in various parts of the country, and have often been seen spinning down from lots and mows where clover has been allowed away.

EEL S Destructive to Barley. Several communications respecting a disease of barley-straw, produced by the punctures of insects, were published in Dr. Pessoon's New England Farmer, in 1829 and 1830 (vol. 8th.). In one of these, from the Hon. J. Merril, of Newburyport, it is stated that the barley in that vicinity yields not much more than the seed sown. Most of the stalks were found to have a number of small worms within them, near to the second joint, and had become hardened in the part attacked. During several years previous to this date the crops of barley in various parts of Essex and Middlesex counties, had been more or less injured in the same way, so as in some places to induce farmers to abandon the culture. It was supposed that the insects had been imported from Bremen, or some other part in the north of Europe. The maggots were found to be transformed into small flies, which were thought by some to be the same as Hessian flies. In the summer of 1831, myriads of these flies were found alive in straw beds in Gloucester, the straw having been taken from the fields the year before. Complaints were made that the insects in these straw beds stung those that slept upon them. But Dr. Harris thinks that the stings must have come, not from the grain-fly itself, but from parasites, vast numbers of which, closely resembling the Encyrtus Destructor, have been found to come out of the diseased straw.

When the barley is about 8 or 10 inches high, the effects of the disease in it begin to be visible by a sudden check in the growth of the plants, and the yellow colour of their lower leaves. If the butts of the straw are now examined, they will be found to be irregularly swollen, and discoloured, between the second and third joints, and, instead of being hollow, are rendered solid, hard, and brittle, so that the stem above the diseased part is impoverished, and seldom produces any grain. Suckers, however, shoot out below, and afterwards yield a partial crop, seldom exceeding one-half the usual quantity of grain. "It is evident," says Mr. Gourgas, "that the soundness of the grain, raised in a blighted field, is not affected thereby in the slightest degree; the seed (eggs) to perpetuate the disease from year to year is lodged in the straw, which, when hatched, are the worms" before mentioned. Dr. Andrew Nichols, of Danvers states, that these worms are about one-tenth of an inch in length, and of yellow or straw colour; and that in the month of November, they appeared to have passed to the chrysalis state. They live through the winter unchanged in the straw, many of them in the stubble in the field, while others are carried away when the grain is harvested. When the barley is threshed, numerous small pieces of diseased straw, too hard to be broken by the flail, will be found among the grain. Some of these may be separated by the winnowing machine, but many others are too large and heavy to be winnowed out, and remain with the grain, from which they can only be removed by the slow process of picking them out by hand.

Dr. Harris, who examined portions of the diseased barley-straw, states that he found each piece to contain several small, whitish maggots, each maggott imbedded in the thickened and solid substance of the stem, a little longitudinal hollow, of the shape of its own body; and its presence was known by an oblong swelling upon the surface. In some pieces of straw the swellings were so numerous as greatly to disfigure the stem, the circulation in which must have been very much checked if not destroyed. Early in the following spring, these maggots entered the pupa or chrysalis state, and on the 15th of June the perfected insects began to make their escape through minute perforations in the straw, which gnawed for this purpose. Seven of these little holes were counted in a piece of straw only half an inch in length. The insects continued to release themselves from their confinement till the 5th of July, after which no more were
FLY, HESSIAN.

Much to his surprise he proved to be minute, four-winged Ichneumon-flies, which are parasitical, or prey, in the larval state; it is their nature thus to lay their eggs on the larval state of the Hessian fly. He had hoped to have obtained the true culprits, the cause of the disease, supposing that the latter were allied to the Hessian fly; but these little insects, while in the larval state, had destroyed them all, and, having finished their appointed task, and undergone their transformations, now made their escape from the straw in the winged form. The scientific name, given to this newly discovered parasitic, was Eurytoma Hordei, so called from Hordeum, the Latin name for barley. It is very much like the parasite (Eurytoma destructor) of the Hessian fly, described by Mr. Say, but is rather larger, of a jet black colour, except the legs, which are blackish, with pale yellow joints. The head and thorax are somewhat rough, and slightly hairy; the hind-body is smooth and polished. The female is thirteen-hundredths of an inch long; the male is rather smaller. It often moves by little leaps, but the hindmost thighs are not thickened. This minute insect is to be reckoned among our friends, being appointed, by an all-wise and provident Creator, to check the increase of the destructive fly that attacks our barley. Though disappointed in my attempts to obtain the latter, in its perfected state, I hail with pleasure the appearance of its mortal enemy. "Although," says Dr. Harris, "the barley-fly has not yet been seen by me, there does not exist the smallest doubt in my mind that it is a two-winged gnat, like the Hessian fly and wheat-fly. Any one, who will compare the history of the latter two with what is known of the barley insect, will arrive at the same conclusion. Both the Hessian fly and the barley insect attack the culms or straw of grain, which they injure to a great extent; and both have a similar four-winged parasite appropriated to them. It is probable that the barley-fly is a species of Cecidomyia, distinct from the Hessian and the wheat-flies."

We have reason to believe, that the maggots of the barley-fly remain in the straw during the winter, and that they take the winged form in the spring, in season to lay their eggs on the young barley: It is therefore important to prevent them from completing their transformations. This may be done by burning the stubble, which contains many of the insects, in the autumn; by destroying in the same way, all the straw and refuse which is unfit for fodder; and by keeping the grain in close vessels over one year, whereby the insects, which are disclosed from the small heavy pieces of straw remaining unwinnowed from the grain, will perish without an opportunity to escape.

FLY, HESSIAN.

One of the most formidable enemies of the wheat crop in the United States, is the far-famed Hessian fly, a small gnat of the family gall-gnats (Cecidomyiidae). The insects of this family are very numerous, and most of them in the maggot state live in galls, or unnatural enlargements of the stems, leaves, and buds of plants, caused by the punctures of the winged insects in laying their eggs. The following account of the Hessian fly, the dread of farmers wherever wheat is cultivated in North America, is chiefly taken from Harris's "Revision of our Insects," and from Poi- rick's valuable paper upon this insect, published in Smithsonian's American Journal of Science, vol. 42. The brief history of the habits and transformations of the Hessian fly will be found to agree essentially with the excellent observations on this insect, written in 1797, by Dr. Isaac Chapman, and published in the Memoirs of the Philadelphia Society for Promoting Agriculture.

"The head and thorax of this fly are black. The hind-body is tawny, and shaded with fine gray hairs; The legs are blackish, but are more or less tinged with yellow at the base, where also they are very narrow: they are fringed with short hairs, and are rounded at the end. The body measures about one-tenth of an inch in length, and the wings expand one-quarter of an inch, or more. Two broods or generations are brought to maturity in the course of a year, and the flies appear in the spring and autumn, but rather earlier in the Southern and Middle States than in New England. The transformations of some in each brood appear to be retarded beyond the usual time, as is found to be the case with many other insects; so that the life of these individuals, from the egg to the winged state, extends to a year or more in length, whereby the continuation of the species in after years is made more sure. It has frequently been asserted that the flies lay their eggs on the grain in the ear; but whether this be true or not, it is certain that they do lay their eggs on the young plants, and long before the grain is ripe; for many persons have witnessed and testified to this fact. In the New England States, winter wheat, as it is called, is usually sown about the 1st of September. Towards the end of this month, and in October, when the grain has sprouted, and begins to show a leaf or two, the flies appear in the fields, and, having paired, begin to lay their eggs, in which business they are occupied for several weeks. The following interesting account of the manner in which this is done, was written by Mr. Edward Tilghman, of Queen Ann county, Maryland, and was published in the eighth volume of the Cultivator, in May, 1841. "By the second week of October, the first sown wheat being well up, and having generally put forth its second and third blades, I resorted to my field in a fine warm forenoon, to endeavour to satisfy myself, by ocular demonstration, whether the fly did deposit the egg on the blades of the growing plant. Selecting a favourable spot to make my observation, I placed myself in a reclining position in a furrow, and had been on the watch but a minute or two, before I discovered a number of small black flies alighting and sitting on the wheat plants around me, and presently one settled on the ridged surface of a blade of a plant completely within my reach and distinct observation. She immediately began depositing her eggs in the longitudinal cavity between the little ridges of the blade. I could distinctly see the eggs ejected from a kind of tube or sting. After she had deposited eight or ten eggs, I easily caught
fly, hessian.

her upon the blade, and wrapped her up in a piece of paper. I then proceeded to take up the plant with as much as I conveniently could of the circumjacent earth, and wrapped it all securely in a piece of paper. After that I continued my observations on the flies, caught several similarly occupied, and could see the eggs uniformly placed on the longitudinal cavities of the blades of the wheat; their appearance being that of minute reddish specks. My own mind being thus completely and fully satisfied as to the mode in which the egg was deposited, I proceeded directly to my dwelling, and put the plant with the eggs upon it in a large glass tumbler, adding a little water to the earth, and secured the vessel by covering it with paper, so that no insect could get access to the interior. The paper was sufficiently perforated with pin-holes for the admission of air. The tumbler with its contents was daily watched by myself to discover the hatching of the eggs. About the middle of the fifteenth day from the deposit of the eggs, I was so fortunate as to discover a very small maggot or worm, of a reddish cast, making its way with considerable activity down the blade, and saw it till it disappeared between the blade and stem of the plant. This I have no doubt, was the produce of one of the eggs, and would, I presume, have hatched much sooner, had the plant remained in the field. It was my intention to have carried on the experiment, by endeavouring to have on the insect from the flax-seed state into the perfect fly again; but being called from home, the plant was suffered to perish. The fly that I caught on the blade of the wheat, as above stated, I enclosed in a letter to Mr. John S. Skinner, the editor of the American Farmer, of Baltimore, who pronounced it to be a genuine Hessian fly, and identical in appearance with others recently received from Virginia.

Dr. Chapman agrees with the writer, in saying that the Hessian fly lays her eggs among the small crenes of the young leaves of the wheat. Mr. Havens, in an article on this insect, which will again be referred to, states, that the fly lays her eggs on the leaves. In the fortieth number of The Connecticut Farmer's Gazette, Mr. Herrick says, 'I have repeatedly, both in autumn and spring, seen the Hessian fly in the act of depositing eggs on wheat, and have always found that she selects for this purpose, the leaves of the young plant. The eggs are laid in various numbers on the upper surface of the silvery-shaped portion (or blade) of the leaf.' His remarks in Professor Latrobe's Journal are to the same effect. Other authorities on this point might be mentioned; but the foregoing are sufficient, in my opinion, to establish the fact, that the Hessian fly lays her eggs on the leaves of wheat soon after the plants are up. 'The number on a single leaf,' says Mr. Herrick, 'is often twenty or thirty, and sometimes much greater. In these cases many of the larvae must perish. The egg is about a fifteenth of an inch long, and four-thousandth of an inch in diameter, cylindrical, translucent, and of a pale reddish brown. Mr. Tilghman was correct in supposing that the eggs would hatch in less than fifteen days, under favourable circumstances; for, if the weather be warm, they commonly hatch in four days after they are laid. The maggots, when they first come out of the shells, are of a pale red colour. Forthwith they crawl down the leaf, and work their way between it and the main stalk, passing downwards till they come to a joint, just above which they remain, a little below the surface of the plant, with the head towards the root of the plant. Having thus fixed themselves upon the stalk, they become stationary, and never move from the place till their transformations are completed. They do not eat the stalk, neither do they penetrate within it, as some persons have supposed, but they lie lengthwise upon its surface, covered by the lower part of the leaves, and are nourished wholly by the sap, which they appear to take by suction. They soon lose their reddish colour, turn pale, and will be found to be clouded with whitish spots; and through their transparent skins a greenish stripe may be seen in the middle of their bodies. As they increase in size, and grow plump and firm, they become imbedded in the side of the stem, by the pressure of their bodies upon the growing plant. One maggot thus placed seldom destroys a plant; but when two or three are fixed in this manner around the stem, they weaken and impoverish the plant, and cause it to fall down, or to wither and die. They usually come to their full size in five or six weeks, and then measure about three-twentieths of an inch in length. Their skin now gradually hardens, becomes brownish, and soon changes to a bright chestnut colour. This change usually happens about the first of December, when the insect may be said to enter on the pupal state, for after this time it takes no more nourishment. Mr. Herrick informs me, that the brown and leathery skin, within which the maggot has changed to a pupa or chrysalis, is long, egg-shaped, smooth, and marked with eleven transverse lines, and measures one-eighth of an inch in length. In this form it has been commonly likened to a flax-seed. It appears, then, from the remarks of Dr. Chapman, Mr. Herrick, and other careful observers, that the maggots of the Hessian fly do not cast off their skins in order to become pupae, wherein they differ from the larvae of most other gnats, and agree with those of common flies; neither do they spin cocoons, as some of the Cecidomyiads are supposed to do. Mr. Herrick, in one of his letters, observes, that 'the pupa gradually cleaves from the dried skin of the larva, and, in the course of two or three weeks, is wholly detached' from it. It is then enclosed within this skin, which thus becomes a kind of cocoon or shell for the pupa, it remains throughout the winter, safely lodged in its bed on the side of the stem, near the root of the plant, and protected from the cold by the dead leaves. Towards the end of April and in the forepart of May, or as soon as the weather becomes warm enough in the spring, the insects are transformed into flies. They make their escape from their winter-quarters by breaking through one end of their shells and the remains of the leaves around them.

"Very soon after the flies come forth in the
for but appears "greenish-white, leaves."

As the leaves of the wheat change from green to yellow, the hessian fly becomes evident, and the larva, which is often a destructive pest, appears on the surface of the field. The maggots pass along the stems of the wheat, nearly to the roots, and then become stationary, and turn to pupae in June and July. In this state they are found at the time of harvest, and when the grain is gathered, they remain in the stubble in the fields. To this, however, as Mr. Haven remarks, there are some exceptions; for a few of the insects do not pass so far down the side of the stems as to be out of the way of the sickle when the grain is reaped, and consequently will be gathered and carried away with the straw. Most of them are transformed to flies in the autumn, but others remain unchanged in the stubble or straw till the next spring. Hereby, says Dr. Coates, 'it appears evident, that they may be removed from their natural situation in the field, and be kept alive long enough to be carried across the Atlantic; from which circumstance it is possible that they might have been imported' in straw from a foreign country. In the winged state, these flies, or more properly gnats, are very active, and, though very small and seemingly feeble, are able to fly to a considerable distance in search of fields of young grain. Their principal migrations take place in August and September in the Middle States, where they undergo their annual transformations earlier than in New England. There, too, they sometimes take wing in immense swarms, and, being probably aided by the wind, are not stopped in their course either by mountains or rivers. On their first appearance in Pennsylvania, they were seen to pass the Delaware like a cloud. Being attracted by light, they have been known, during the wheat harvest, to enter houses in the evening in such numbers as seriously to annoy the inhabitants.

'The old discussion, concerning the place where the Hessian fly lays her eggs, has lately been revived, in consequence of a communication made by Miss Margaretta H. Morris, of Germantown, Pennsylvania, to 'The American Philosophical Society,' of Philadelphia. The following remarks upon it are extracted from a report made to the same society, and published in their Proceedings for November and December, 1840. 'Miss Morris believes she has established that the ovum (egg) of this destructive insect is deposited in the seed of the wheat, and not in the stalk or culm. She has watched the progress of the animal since June, 1836, and has satisfied herself that she has frequently seen the larva within the seed. She has also detected the larva at various stages of its progress, from the seed to between the body of the stalk and the sheath of the leaf. According to her observations, the recently hatched larva penetrates to the centre of the straw, where it may be found of a pale greenish-white, semi-transparent appearance, in form somewhat resembling a silk-worm. From one to six of these have been found at various heights from the seed to the third joint.' Miss Morris's communication has not yet been published in full; but, from the foregoing report, we are led to infer that the egg, being sown with the grain, is hatched in the ground, and that the maggot afterwards mounts from the seed through the middle of the stem, and having reached the hollow of the straw to the outside, where it takes the pupa or flax-seed state. The fact that the Hessian fly does ordinarily lay her eggs on the young leaves of wheat, barley, and rye, both in the spring and in the autumn, is too well authenticated to admit of any doubt. If, therefore, the observations of Miss Morris are found to be equally correct, they will serve to show, still more than the foregoing history, how variable and extraordinary is the economy of this insect, and how great are the resources wherewith it is provided for the continuation of its kind." (Harris.)

Dr. B. H. Coates of Philadelphia, whose attention has been recently drawn to the Hessian and other flies destructive to wheat crops, states that a number of examinations made in the vicinity of Philadelphia during the summer of 1841, showed the presence of a pale yellow larva in the hollow of the straw of wheat, which he considered as proved to be the same with that which is ultimately converted into the Credomyia destructor of Say, and the Hessian fly of our cultivators. In many instances, "communicated to him by Miss Morris," referable, perhaps, to a peculiarity in the season, the animal went through all its stages before escaping from the cavity; "thus, according," says Dr. Coates, "irrefragable evidences of the identity of the species." In no case known to Dr. C. had any thing resembling a caterpillar or maggot, or any thing apparently capable of locomotion, been found under the sheath of the leaf; the body observed was always immovable and fixed in a depression of the straw. (Proceedings of the Am. Phil. Soc.) *

"Various means have been recommended for preventing or lessening the ravages of the Hessian fly; but they have hitherto failed, either because they have not been adapted to the end in view, or because they have not been universally adopted; and it appears doubtful whether any of them will ever entirely exterminate the insect. It is stated in the before-mentioned report to the Philosophical Society,' that Miss Morris advises obtaining 'fresh seed from localities in which the fly has not made its appearance,' and that 'by this means the crop of the following year will be uninjured; but in order to avoid the introduction of struggling insects of the kind from adjacent fields, it is requisite that a whole neighbourhood should persevere in this precaution for two or more years in succession.' (Harris.)

It seems to be generally admitted that the variety of wheat called Mediterranean, introduced a few years since into the United States, where it is mostly extensively cultivated, resists the attacks of the Hessian fly. Hence it may be sown very early in the fall, long before it would be safe to sow the common varieties, by which another great advantage is gained, in its escaping the rust and mildew so apt to
FOAL.

affect crops which are backward in the time of ripening.

FOAL (Su. Goth. fol.; Sax. rola). The young of the horse kind; the male being termed a colt foal, and the female a filly. The foal and its mother should always be well fed, and two feeds of corn, at least, be added to the green food which they get, when turned out after their work at night. The growing colt should continue to have liberal nourishment; bruised oats and bran should form a considerable part of his daily provender. In five or six months, according to the growth of the foal, it may be weaned. It should then be housed for three weeks or a month, or turned into some distant rick-yard. The process of breaking in should commence from the very period of weaning; and the foal should be daily handled, partially dressed, accustomed to the halter, led about, and even tied up; for on this much of the tractability, good temper, and condition of the horse will depend. After the second winter, the work of breaking in may commence in good earnest.

Management of Foals after Weaning.—The principal object with most breeders is to have their stock large and powerful at an early age. It is really wonderful what may be done towards effecting this by means of good food judiciously supplied, proper shelter, and liberty of range in favourable weather. It is natural to suppose, when a foal is first taken from its dam, that it will, in some degree, fall away in condition and lose flesh; the nutritive properties of its “mother’s milk” cannot be taken from it without affecting its yet tender constitution. To guard against this, every attention must be directed to the quality as well as quantity of food which is presented to it; that which contains most nourishment must be provided, and although the bulk of hay which a foal consumes is very trifling, it should be of the best quality. For foals, when they are first weaned, linseed gruel should be their constant beverage, and, indeed, it cannot be too highly recommended for all horses. A liberal allowance of oats is necessary, and these should be quite hot. The root of the foal will eat at least two quarters per day; and, as they increase in age, this allowance may be augmented. The seeds which are left from the linseed-gruel, should be given with the corn. I have frequently recommended the practice of bruising the oats, and must certainly repeat it, even in opposition to the arguments of some persons who are averse to it. Bran mashes may be given at least once a week, and in some instances more frequently. Carrots will likewise be found a very proper food for young stock, and should be given once or twice a day. Too long a continuance of the same food cloyes the appetite. Boiled barley is found to be very nutritious food, and most horses are very fond of it. As an alternative, it may be given with great advantage, if foals do not consume their corn with their usual appetite. It requires to be well boiled for two or three hours in a small quantity of water, frequently replenishing it that the grain may not burn, and constantly stirring it that every grain may undergo an equal process; it may be considered sufficiently boiled when all the corns have burst, and, when given, should have a little bran or finely-cut hay mixed with it. About ten days or a fortnight after they are weaned, each foal should have a gentle dose of physic—one drachm to a drachm and a half of afoes, with a drachm of Castile soap, and the same quantity of ginger, will generally be found sufficient.

FOALING. A term applied to the act of parturition, or bringing forth young in the mare. Good feeding and moderate exercise are found to be the best preventives against slinking, which is most prevalent when half the time of pregnancy has elapsed. See Absorption. If a mare has been regularly exercised, and apparently in health while she was in foal, little danger will attend the act of parturition. If there be false presentations of the foetus, or difficulty in producing it, it will be better to have recourse to a well-informed veterinary practitioner, rather than injure the mother by the violent and injurious attempts which are often made to relieve the animal. As soon as the mare has foaled, she should be turned into some well sheltered pasture, with a hovel or shed to run into when she pleases; and, as supposing she has foaled in April, the grass is scanty, she should have a couple of feeds of corn daily. The mare may be put to moderate work a month after foaling.

FOODER (Germ. futter; Sax. futter; from panea, to eat; Irish, foder, straw; Celt. foth). In agriculture, the ordinary food given to cattle, which consists of the stems and leaves of plants, such as clover, hay, chopped straw, dried breads and tops of Indian corn, &c.; the culmiferous stems of the grasses, the haum of legumes, potatoes, &c.; Grain, beans, turnips, and other articles which present nourishment in a more concentrated form, are not included under the term fodder, but are rather known as solid food. See Food.

FOG (Dan. fog). In meteorology, a dense vapour near the surface of the land or water. Fogs in general are the consequence of the nocturnal cooling of the atmosphere. The air, by its rapid cooling, becomes surcharged with moisture; a part of which being condensed in the form of a cloud, gives rise to the ordinary fog. During the day the heat of the sun generally disperses the fog, because the quantity of moisture which the air is capable of holding becomes considerable in proportion as its temperature is increased. In calm weather the surfaces of rivers, lakes, &c., are frequently covered with fog. The reason is this. During the night the air is colder than the water; the strata of air in contact with the water are consequently heated, and become saturated with moisture. The mixture of the vapour with the air, together with its elevation of temperature, renders the air specifically lighter. It rises in consequence, and mixing with the cold air in the superior strata, is cooled, and has its moisture condensed. The cloud or fog resulting from this precipitation can only rise to a small height, because the uniformity of temperature is soon restored. Hence it is easy to see how winds, or a great agitation of the water, prevent the formation of fogs over the surface of water. In the equinoctial regions, fogs some
FOGGAGE.

FOOD.
times continue during a considerable part of the year. In the Polar seas thick fogs often prevail, even during the warmest months; and they are so dense that objects frequently cannot be distinguished at the distance of a few yards. (Brande's Dict. of Science.)

FOGGAGE (Low Lat. foggium). Coarse or rank grassy folds formed in the summer or autumn. The practice of fogging grasslands for the winter support of stock has been found highly useful.

FOGGING. A common word in the north, that properly signifies the grass which immediately springs after the hay-crop has been taken, but it is sometimes used for the long grass remaining in the pastures till winter. (See Artic-Grass.) It is also used for moss, in some parts of Scotland; thus a fog-house means a house built or lined with moss.

FOGGER. A peculiar practice in the management of grass-lands, confined chiefly to the district of South Wales. It consists in keeping the whole growth of grass in upland meadows free from either scythe or stock, and eating it in the following winter. Arthur Young states, that many years ago, he knew a Suffolk clergyman, who was in the regular habit of this singular practice, and spoke of it as a most profitable one. He has, he says, tried it thrice, and with success; and he finds that it thickens the herbage greatly; and yields far more valuable winter and spring food than any person would expect, who never tried it. But it should be practised only on dry or tolerably dry land.

FOLD (Sax. reatbe). A temporary pen or enclosure for keeping cattle or other agricultural animals together, either for the purpose of confinement during the night, or jointly for protection and feeding. Sometimes, also, sheep are folded for the purpose of manuring. Sheep-folds are of two kinds; either houses or sheds set apart for that purpose adjoining to the farm or farm-yard; or they are movable, forming a whole fold, or flock, of sheep, which are folded from the farm, and are ready to fold them, as soon as they are brought up together, and the fold is formed. The temporary fencing or barrier of which movable folds are constructed, is most commonly wooden hurdles; but sometimes, when the fold is only to contain ewes and lambs, netting stretched between posts is made use of, there being a strong rope fixed to the lower parts of the post, close to the ground, to which the under edge of the netting is attached, while its upper edge is fastened to a rope stretched along the tops of the same post. Netting is by far the cheapest and neatest substance for barriers for folds. (See Hurdles.) Mr. Children has recently advocated a system of shed-feeding (Joum. Roy. Agr. Soc. vol. i. p. 40); and there is little doubt that sheep, in common with all live stock, suffer more from the effects of wet and cold, when feeding in exposed situations, than is commonly supposed.

FOLDING. The practice of confining sheep and other animals upon land, by means of hurdles, &c., for the purpose of feeding on it and manuring it. The practice of folding sheep on naked fallows, with a view to manuring them, is still common in several parts of England; but the more improved sheep farmers consider that it deteriorates the wool and impedes the fattening of the sheep, by keeping them for the greater part of every night wholly without food. Others, however, assert that folding is not injurious to sheep, if they are kept in a good pasture, for at least six hours every day, and not exposed to the cold in the evening, or kept in the fold too long in the morning. In some large arable land farms in Hampshire and other counties, folding is still considered necessary, and large flocks of breeding ewes are kept specially for that purpose. Sheep are occasionally penned or folded on young wheat, but more commonly on turnips, a certain portion being enclosed, sufficient for them to eat off in one or two days.

FOLD-YARD. The yard where cattle of different sorts are confined and fed during the winter season. Yards of this nature should be properly fitted up with convenient sheds and racks for the animals to eat their fodder from, and have suitable divisions for containing different denominations of cattle, or other live stock. See Farm-Yard.

FOOD (Sax. tosc). All substances susceptible of digestion and assimilation may come under the denomination of food. Animals require, for their support and developement, atoms or elements highly organized. The food of all animals, under all circumstances, consists of portions of organized matter. Vegetables, on the contrary, require for their support elements derived from the complete destruction of organized substances, whether animal or vegetable, through the processes of putrefaction and decay. The proximate principles of organic bodies, on which their nutritive powers depend, are comparatively few. Although the articles employed in different countries for the support of animal life are almost infinitely various, their sustaining powers may be referred to certain substances capable of being separated from the chemical analyses and tests. Amongst the proximate elements of vegetable food, gluten and its modifications, starch, gum, sugar, and lignin or woody fibre, are by far the most important; and amongst those of animal food, fibrin, albumen, gelatin, and their modifications, together with fats and oils, which are common to both kingdoms of nature. To illustrate the actual simplicity of our food, as compared with its apparent multifariously and complexity, it may suffice to state that wheat, and almost all the esculent grains, consist principally of starch, foreign matter; that the same ingredients are found in many fruits and roots; that sugar, gum, or a relation of gum, which is called vegetable jelly, together with minute traces of aromatic principles which give flavour, and more or less abundance of water and of vegetable acids, are the chief component parts of apples, peaches, currants, &c., and all pulpy and juicy fruits; a very few also contain oil. Then, as regards animal food, the muscular fibres of various animals closely resemble each other in composition and nutritive power: in some cases texture merely, and in others smell and taste, concur upon them their relative digestibilities and their different aspects and flavours.
FOOD.

Alburn or fibrin and gelatin, small proportions of saline bodies, and a large quantity of water, are found in them all.

It often happens that the truly nutritious part of food is so combined with or protected by indigestible matters as to escape the solvent powers of the stomach, unless previously prepared and modified by various chemical and mechanical agents. Indurated woody fibre, for instance, or lignin, as chemists call it, will often resist the joint action of the stomach and bowels, and pass through the alimentary canal with scarcely any alteration. The husks of many seeds and fruits are composed almost exclusively of this material. This is the case with the kernels of the apple, pear, &c.; the seeds of the currant, gooseberry, melon, and so on; the skin or husk of peas, beans, &c., and of wheat, barley, and oats; so that unless the woody part is either broken down by the teeth or previously removed, the food which it envelopes is protected in some degree from the solvent action of the secretions of the stomach. This is a wise and curious provision in nature, for birds in this way become the carriers of seeds, which pass through them not only undigested, but even retaining their vegetable powers; and in this way uninhabited and sterile portions of the globe may gradually become clothed with verdure, and shrubs, and trees.

Hence the advantage derived from bruising the corn given to live-stock. Bones are highly nutritious, but, unless broken into very small fragments by the masticatory powers of the animals which eat them, they too would elude digestion.

There is another important point in the history of food, which is, its ultimate composition. Four elements only are principally concerned in the production of the food of animals; these are carbon, hydrogen, oxygen, and nitrogen. Among vegetable substances, gluten (including vegetable albumen) is the only one which abounds in nitrogen; gum, sugar, starch, and the rest, are constituted of carbon, hydrogen, and oxygen only. There are two very singular points in reference to the chemical history of food: the one is, that no animal can subsist for any length of time upon food which is destitute of nitrogen; and the other, that a certain mixture of different food is absolutely essential. Habit, as is well known, will do much in accommodating the stomach to particular descriptions of food: many persons live exclusively, or almost so, on vegetables, others on animal matters, and particular kinds of diet are forced on the inhabitants of many regions of the globe; but as far as we are concerned, a due mixture of vegetable and animal matter is not only most palatable, but most conducive to health. Nothing is fit for food which has not already undergone organization; and water, though an essential part of the food of all animals, is obviously not in itself nutritious, though it performs the extremely important function of dissolving nutritive matter, so as to render it conveyable by the lacteals and other absorbents into the blood.

The subjoined table will serve to show the comparative value of the principal cereal and other grasses, legumes, roots, &c. (Davy, Elem. Ag. Chem. 150.)

The following table represents the relative proportion of solid digestible matter contained in 1000 parts of the different articles of food which are enumerated. Upon an average, the nutritive matter in a pound of meat is not more than four ounces. This, however, applies only to raw meat; for, when dressed, a considerable portion of its constituent water is dissipated.

A very interesting report on the nutritive properties of food was recently presented to the French Minister of the Interior, by MM. Percy and Vauquelin, two members of the Institute. The result of their experiments is as follows:

In bread, every 100 lbs. weight is found to contain 80 lbs. of nutritive matter. Butchers' meat, averaging the various sorts, contain only 35 lbs. in 100. French beans (in the grain), 92 lbs. in 100; broad beans, 89; peas, 93; lentilles, 94 in 100. Greens and turnips, which are the most aqueous of all vegetables used for domestic purposes, furnish only 8 lbs. of solid nutritive substance in 100. Carrots, 14 lbs.; and what is very remarkable is, that in opposition to the hitherto acknowledged doctrine, 100 lbs. of potatoes only yield 25 lbs. of substance valuable as nutrition. 1 lb. of good bread is equal to 2½ lbs. or 3 lbs. of the best potatoes; and 75 lbs. of bread and 30 of meat are equal to 300 lbs. of potatoes; or, to go more into detail, ⅔ of a lb. of bread and 5 oz. of meat are equal to 3 lbs. of potatoes. 1 lb. of potatoes is equal to 4 lbs. of cabbage and 3 lbs. of turnips; but 1 lb. of rice, broad beans, or French beans (in grain), is equal to 3 lbs. of potatoes.

In the smaller roots, such as carrots, &c., but especially turnips, sugar is the leading nutritive matter; and the common fruits contain sugar, gum, albuminous matter, and acids, together with a highly attenuated form of woody fibre or lignin, which in that state is probably digestible. The comparative nutritive properties of the most common fruits will be seen by a reference to the annexed table.

On fattening Animals.—There is a very great difference in the quantity of food which animals require, and in the time which they can pass without it. In general, those animals which are the most active require most, and those which are most indolent require least food. The cause of this is pretty obvious; the bodies of animals do not remain stationary, they are constantly wasting, and the waste is proportioned to the activity of the animal; hence the body must receive, from time to time, new supplies in place of what has been carried off. The use of food answers this purpose. Almost all the inferior animals have particular substances on which they feed exclusively. Some are herbivorous, some are granivorous, and others, again, are carnivorous.

From various experiments we have the following result:

A horse will consume as much food, besides corn, as 8 sheep.
A cow — — — — — — — — — — — — — — — 12
A fattening ox — — — — — — — — — — — — — — 10
A three-year-old heifer — — — — — — — — — — 6
A one-year-old heifer — — — — — — — — — — — 4
A calf — — — — — — — — — — — — — — — — — 2

There are some rules which may be advantageously adopted in feeding animals, which, however obvious they may be, are too often neglected. 1. Food should be so prepared that its nutritive properties may be all made available to the use of the animal; and not only so, but appropriated with the least possible expenditure of muscular energy. The ox that is obliged to wander over an acre to get the food he should find in two or three square rods—the horse that is two or three hours eating the coarse food he should swallow in fifteen minutes if the grain were ground or the hay cut as it should be—the sheep that spends hours in making its way into a turnip, when, if it were sliced, it would eat it in as many minutes—the pig that eats raw potatoes or whole corn, when either cooked could be eaten in one quarter of the time, may indeed fatten, but much less rapidly than if their food were given in a proper manner. All food should be given in such a state to fattening animals, that as little time as possible, on the part of the animal, shall be required in eating.

2. From the time the fattening process commences, until the animal is slaughtered, he should never be without food. Health and appetite are best promoted by change of diet rather than by limiting the quantity. The animal that is stuffed and starved by turns may have streaked meat, but it will be made too slowly for the pleasure or the profit of the good farmer.

3. The food should be given regularly. This is one of the most essential points in feeding animals. If given irregularly, the animal will consume his food, but he soon acquires a restless disposition, is disturbed at every appearance of his feeder, and is never in that quiet state so necessary to take on fat. It is surprising how readily any animal acquires habits of regularity in feeding, and how soon the influence of this is felt in the improvement of his condition. When at the regular hour the pig has had his pudding, or the sheep his turnips, they compose themselves to rest, their digestion is not unseasonably disturbed, or their quiet broken by unwonted invitation to eat.

4. The animal should not be needlessly intruded upon during the hours of eating. All animals fatten much faster in the dark than in the light, a fact only to be accounted for by their greater quiet. Some of those creatures that are the most irritable and impatient of restraint while feeding, such as turkeys and
FOOD OF PLANTS.

Geese, are found to take on fat rapidly when confined in dark rooms, and only fed at stated hours by hand. There is no surer proof that a pig is doing well than to see him eat his meal quickly and then retire to his bed till the hour of feeding returns. Animals, while fattening, should never be driven, nor may they ever be fed at unseasonable hours, and, above all, things, never be allowed to want for food.

The following table will show the ultimate composition of those proximate principles which have been already adverted to as constituting the nutritive parts of food.

See also the heads CATTLE, FOEDER, SHEEP, SWINE, HORSES, &C. (Branden's Dict. of Science; Davy's Ag. Chem.)

FOOD OF PLANTS. See EARTHS, GASES, SALT, WATERS, AND MINERALS, THEIR USES TO VEGETATION. Plants absorb their nutrition, from the air and from the soil; they become the food of the granivorous tribes, and from these men derive the great bulk of his animal subsistence.

FOOL'S PARSLEY. Common Lesser Hemlock (Ethyins cynapium). Pl. 10, q. A numbliferous plant, common in gardens, waste grounds, and cultivated fields, and so called from its resembling parsley enough in appearance to deceive ignorant persons. It is an annual weed, with a tapering whitish root; stem round, often purplish a foot high; flowers white; the berries of a dark livid green, and fiddly. The plant is poisonous, acting like hemlock upon the human system, and is easily known by the involucres having each three linear leaflets, which are placed next the circumference of the umbel. It is eaten by cattle and sheep, but is pernicious to the latter.

FOOL'S STONES (Oroch moria). See TWAYBLADE.

FOOT (Sax. foot; Germ. fuss; Dutch fote). A linear measure, which, since the term is employed in almost all languages, has doubtless been derived from the length of the human foot. Though the denomination is the same, the measure itself varies considerably in different European countries. In all of them, however, it is divided, like the English foot, into 12 equal parts, or inches. See WEIGHTS and MEASURES.

Foot is also the lower part of the limbs of an animal, which afford support, and enable it to move with ease and convenience from place to place. An excellent article on the anatomy of the feet of the horse, by Mr. Dick, will be found in the second volume of the Quart. Journ. of Agr. p. 214. The best and most natural form of the foot of the horse is that where the bottom approaches to a circle; it is most complicated in its structure, and liable to a variety of diseases. See the heads CANKER, CORNS, CRACKS, SHOEING, AND DISEASES OF THE HORSE.

FOOT-ROT. See SHEEP, DISEASES OF.

FOOT-TRENCHES. A term signifying small superficial drains, about a foot wide.

FORCING. In horticulture, the art of accelerating the growth of plants so as to obtain fruit, vegetables, or flowers at seasons when they are not produced naturally in the open air. The practice appears to be as old as the time of the Romans. In England forcing seems to have been practised from a very early period. At the present time forcing is carried on in Britain, and in analogous climates throughout Europe and North America, chiefly under glass roofs. Structures for forcing are known, as frames, pits, and houses, all of which have glass roofs: but there are also structures for forcing without glass roofs, such as cellars and sheds for growing mushrooms in the winter season; and also sea-kale, rhubarb, blanched succory, and such other stalks or leaves of plants as are eaten in a blanched state, and consequently do not require much light.

FORCING PITS. Instead of forming hotbeds with open sides, pits of brick-work and other material have very generally been constructed for containing the fermenting mass of dung necessary for forcing.

Mr. Flanagan, gardener to Sir T. Hare, of Stow Hall, Norfolk, and Mr. West, who holds the same situation under the Marquis of Northampton, at Castle Ashby, have each proposed plans of pits, of which that of the first horticulturist is the least expensive; that of the latter more economical in other respects, not only as preventing the waste of heat, but the best mode of applying it. It may be laid down as a fundamental principle that, in applying heat, it should always be brought to the bottom of the body to be heated.

Mr. Flanagan only allows the heat of fermenting dung to be employed, the steam being prevented entering the frame. One advantage arising from this he states to be, that fresh-made dung may be employed, and, consequently, the loss sustained by any preparation is prevented. If, however, it be a fact that the steam of dung is rather beneficial than otherwise, fresh fermenting dung can be used, without any detriment that I am aware of, in other pits of which the following are plans. Mr. F. describes his pit as follows:—It is 4 feet deep within; the lowest 10 inches of solid brick-work sunk in the earth; the remainder is a flue, 3 inches wide in the clear, carried entirely round the pit; the inner wall of which, forming the sides of the pit, is 4-inch work, well b阿森ed in mortar, and pointed, to prevent the steam penetrating; the outer wall of the flue is also 4-inch, but open-work, to admit the steam and that of dung-coatings into the flue, the top of which is rendered tight by a covering of tiles, &c. The frame rests on the external wall of the flue. The cavity of the pit, which is kept dry by means of drains, is 9 feet 2 inches long, 2 feet 501.
8 inches wide, and 4 feet deep. It is filled with broken bricks, to within 18 inches of the top; then a foot of short cold dung, 6 inches of very rotten dung, trod down so as to admit half an inch depth of coal ashes, for preventing the intrusion of any worms that may be in the dung, complete the structure. (G. W. Johnson's Kitchen Garden.)

FOREHAND. In horsemanship, that part of the animal which is before the rider.

FOREST (Germ. forst; Fr. forêt; Ital. foresta). Strictly an extensive surface covered naturally by trees and undergrowth, as opposed to one which is kept up by art, but indiscriminately used for any very extensive tract covered with trees. The utility of timber plantations to a commercial nation is very great, as, by the quantity of timber they afford, a considerable expense may be saved which must otherwise be incurred by the importation of materials for ship-building. (See Plantation.) In former times the greater part of every country in the temperate parts of Europe was undoubtedly covered with forests; and these, by harbouring and nourishing wild animals of every description, particularly wild swine, afforded a principal part of the food of man. With civilization, however, they gradually disappear before the increase of pasture or arable land. In every country a large portion of the forests belonged to the government, and formed a main source of its revenue. This is still the case in France and Germany, and, till lately, it was also the case to a certain extent in Britain. Hence extensive tracts in England still bear the name of forest, though they are now in a state of cultivation, and in a great measure without trees.

The royal forests of Britain occupy about 125,000 acres of land. There are 32,768 acres of forest land enclosed and planted, principally with oak, and with other trees where the soil is not adapted to oak. There are 6211 acres of other freehold land belonging to the crown, which are also appropriated to the growth of timber, making in all 38,979 acres, the whole of which have been enclosed and planted within the last twenty years.

For an account of the existing forests of England, see "Statistics of the British Empire." (Brit. Itch, vol. iii. article "Plantations," pp. 83, 85; Brande's Dict. of Science.)

FOSSE. A large ditch or moat; also a waterfall.

FOUL. Cock and hen (Phasianus colchicus). Fowls were originally natives of Persia and India. They are most valuable to the farmer as yielding profit in eggs, broods, and feathers. The varieties of the common fowl in England are very numerous, and are distinguished from one another by their size, colour, and fecundity. Fowls should be kept very clean and dry in the hencoop, and particular care must be taken to furnish them with clean, sweet water; foul water produces that fatal disorder among chickens called roup, or gapes, which is known by the chick gasping for breath, and dying in a few hours. No remedy has yet been discovered for this disorder; therefore care and cleanliness should prevent it. Foul water, and a scarcity of water, are also causes of the pip in hens, and originate all their diseases. Poultry of all sorts should have clean, sweet houses to retire into during the night, and in seasons of wet. Warmth is necessary to the comfort and well-doing of poultry. If hens are kept with care, and have clean, quiet places to deposit themselves in, they will lay regularly, and repay all trouble. One cock is sufficient for ten hens. He should be chosen with care. A good cock should be well-sized, carrying his head high; he should have a quick, animated look, a strong shrill voice, the comb of a fine red, broad breast, strong wings, legs thick, and his bill thick and short. (Mann's Domestic Poultry, p. 230.) The vigour of the cock lasts three years; he must then be superseded, and a fine spirited youthful successor installed in his room. A cock is at full age at three months old. Three sorts of hen are useful. The common hen, whose proper signs should be in having a large head, blueish feet, sharp eyes, and pendant comb. The tufted hen, for eating, as she does not lay much, therefore fattens well; and the large white Dorking breed, which always fetches a higher price in the market. The Dorking fowls are distinguished by having five claws on each foot. Equal to the Dorking in estimation (says Professor Low) are the Poland fowls. Their colour is black, their heads flat, and surmounted with a crown of feathers. They are a very useful variety; prolific of eggs, but less inclined to sit than those of any other breed. All others are kept more for show than for use. The bantam is a little Indian breed, very delicate to eat, but, from the smallness of its size, not of any economical importance.

The Chitagong, or Malay fowl, is the largest breed that has yet been brought to England, but the flesh is regarded as inferior to that of the Dorking and Poland. Fowls should not be allowed to wander much; they lay better and more regularly when confined to their own yard. Their food should be given with great regularity at sun-rise and sun-set, and they should be fed under cover during rain or high winds. During harvest their portion of food is always diminished. All sorts of pot-herbs, boiled, in the washings of dishes, mixed with bran, and then drained, is excellent; the paste warmed up as required, while sweet. Well boiled mealy potatoes, buckwheat, barley, whole or ground, refuse of fruit, bread, offal from the kitchen, &c., is taken greedily. Let all their food be fresh of its kind.

The laying time in England begins about February. A hen gives notice of her intention by being busy and restless, and talking to herself for some time, and her comb becomes very red. Her cackling soon gives notice that the deed is done. Let her have a dark, quiet box to lay in. The moulting season begins in autumn, when the hen ceases to lay for some time: the whole feathered tribe are then drooping and dull, till the new feathers have replaced the old ones. A hen is old at four years of age: for three years she is valuable, and in her fourth year she must make way for younger birds. A hen sits three weeks; her disposition to sit is soon discovered, by her placing her-
self upon any eggs she can find, and remaining thereon instead of roosting. She should be placed upon fresh eggs, unless allowed to sit as nature directs upon her own natural number, which rarely exceeds eighteen; but if one egg alone is allowed to remain in the nest she will continue to lay many more before she wishes to sit. If the brood is hatched irregularly, the firstlings should be kept in flannel near a fire all day, till the others come forth, but they should be returned to the mother at night. The hen and her brood should be kept warm, and be cooped out of doors only in dry, fine weather. They should be fed for some days on bread crumbs, with some finely chopped leeks, and be carefully supplied with clear, clean water daily. Boiled barley, and boiled rice, &c. succeeds, till in about three weeks they are sufficiently strong to be turned into the poultry-yard. When the young chickens get their head feathers, they are out of danger of all infantile disorders. Nothing is so requisite as well-scrubbed, cleanliness and good water. Fowls fattened for the table should be put into coops for a fortnight or three weeks, and fed upon good barley-meal, moistened with milk or water, and lard. Give it four or five times per day, sufficiently moist to require no drink with the food.

Eggs are preserved any length of time, by greasing them well over with butter or lard, when warm from the nest. It keeps out the air. Fresh laid eggs are easily known by holding them up to the light of a candle. If the inside appears transparent and fluid, and the yolk in the centre, it is a fresh egg. If it looks turbid, it is a stale one. If, also, an egg held up against a candle shows a small vacancy at the top of it within, it will produce a male bird: if the little vacancy is observed at the side of the egg, it will prove a female. (Main's Dom. Poultry, p. 253.) See Eggs. Every poultry-yard should have a bed of ashes deposited in a corner: the fowls delight in a dunghill and an ash-hole; the former produces seeds and insects, and the latter calcareous matter, and destroys their vermin by its sharpness, as they revel in its rough particles. See CACON.

There is a communication in the Farmer's Cabinet, (vol. ii. p. 95,) upon keeping hens, and the profits from eggs, from a poulterer in Eaton, Massachusetts, which contains much useful information. On the lst of January, says the writer, I had ten hens and one cock. In the spring three of the hens were suffered to set, which left seven to experiment with. The three which set raised 21 chickens, which were sold for 121 cents each, when about the size of quails. The sooner he observes, you will sell chickens the better, since they do not bring prices corresponding with their increase in size. The seven hens which did not set, laid 100 dozen of eggs. During half the time in winter the fowls were fed upon boiled potatoes and bran or meal mixed together with warm water, and as the place where they were kept was well sheltered, none were lost by the dough freezing in their claws or crops. For the remainder of the time oats were given them, which the writer considers better for fowls than Indian corn, having tried both. The oats were first allowed to soak in warm water for three or four hours, till well swelled, after which they were given to the fowls. Treated in this way he considers one bushel of oats will go as far as a bushel and a half of corn. Hens, &c. should never be allowed to roost in stables or kept near cattle, as they communicate their vermin to these, which worries and prevents them from growing fat.

FOWL, GUINEA, or PINTANO (Numida meleagris). These birds are very wild and restless in their nature, owing to their native habits. They are shy, and love to make their nests in dark, obscure places, far from home; for which reason their eggs are generally placed under a common hen to be hatched and fostered. They give no notice of laying or setting. A brood of Guinea fowls is an excellent guard. They love roosting in the trees; and at night, if any footstep disturb them, their loud cries are sure to give notice to the farmer that a trespasser is attempting to get at his game. The Guinea fowl is delicate eating, and is in fine season about Lent. The young chickens must be treated in the same manner and with the same food as young turkeys, and they must be kept warm and dry. In fattening, they should be shut up in a house for a fortnight, and fed four or five times a day with sweet barley-meal, moistened with milk and good lard. They pine if confined any length of time. The great drawbacks to the rearing of Guinea fowls are the vigilance required to watch for their nest, and the harsh screaming of their cry.

FOWL, PEA (Phasianus Leb). Native of India, tender in infancy, but soon inured to our climate, as they become older. From their native wild habits, they love to lay their eggs in woods or coppices far from home. As the hen covers her eggs over with dead leaves after laying them, and generally deposits them under a bush, without the ceremony of making a nest, she must be closely watched, and each day her fresh egg should be withdrawn, and an egg cut in chalk substituted, and covered over again with the leaves. The eggs should be placed under a common hen for safety, both on account of the fox, and because the pea-hen would lead the young ones to ramble as soon as they had escaped from the shell. The best food for pea-chicks is barley-meal made into a paste, and mixed with sweet curd, and finely chopped, hard-boiled eggs. They are also exceedingly fond of the large horse ant and its eggs, which in England are found in woods, deposited in little hillocks of small leaves and twigs. All the tribes of wild birds, such as pea-fowl, turkeys, pheasants, &c. love ants: it is their natural food. Two or three handfuls of their eggs twice a day, makes a good variety with their usual food. Keep the young pea-fowls well housed while under the mother's care: when they grow up, they prefer roosting in trees or on buildings. If a pea-hen is allowed to brood her own chickens, she should be kept under a coop for three weeks at least, to prevent her rambling. Pea-fowl will feed well on any kind of corn. They are exceedingly destructive in a garden. Our ancestors considered them very delicate eating.
FOUL'S DUNG.

See Guano and Piggon's Dung.

FOX-EVIL. A disease in which the hair falls off.

FOXGLOVE, COMMON (Digitalis purpurea). A very handsome biennial plant, blooming purplish-crimson, or occasionally white flowers, from June to September. In England it is found wild in pastures and about hedges or banks, on a graviely, sandy, or chalky soil. In gardens it is easily propagated by seed.

The lesser yellow foxglove (D. pareiflora) is a native of Italy, and perennial: grows three feet high, blooming yellow flowers in June and July. It may be propagated from seed.

The large yellow foxglove (D. ambigua), with larger flowers, is also a perennial, growing three feet high.

The medicinal qualities of the foxglove are diuretic, powerfully emetic, and narcotic; and, under proper management it is a most useful medicine. The leaves are inert in the first year of the growth of the plant. They are sometimes used externally as cataplasms for resolving scrofulous tumours. As every part of the foxglove is poisonous, children ought to be warned against chewing it. No person not qualified to practise medicine should venture to prescribe foxglove.

FOX-TAIL GRASS (Setaria glauca). A common American grass, with a bristly head, found in cultivated grounds, old stubble-fields, orchards, &c., flowering in July. Its root is annual, and the stem grows 2 or 3 feet high. When mature it has a tawny, or orange colour.

Another species of fox-tail is popularly called green fox-tail, or butter-grass (Setaria viridis). Its general resemblance to the species first-named, render it liable to be passed by as a green variety of that plant.

A species of Setaria (S. verticillata), commonly found about gardens and cultivated lots in the Middle States, has teeth on the bristles, which cause the spikes to adhere to objects with which they come in contact.

Another species called German Setaria, millet of Bengal grass, is occasionally found in fallow fields. Dr. Muhlenburg supposed this annual plant might be a variety of the green fox-tail, to which Dr. Darlington thinks it certainly allied. Some years ago, the Bengal grass was introduced into the Middle States as an object of culture, and, for a time, excited much interest among farmers. It was soon found, however, not to be as valuable as the usual summer crop, of which it occupied the place, and its cultivation is now pretty much abandoned. The seed is sown in the early part of May.

Several other species of this genus are found in the United States, of which one called the Italian Setaria is met with along the river Delaware, distinguished by its very large spikes. The others are southern plants. None of them, except the German setaria, possess any value to the agriculturist. (Flor. Cestric.)

See Alopecurus.

FRANCE, THE AGRICULTURE OF.—Although the two kingdoms of Britain and France, are such near neighbours, and enjoy a soil so similar, yet the agriculture of each differs very materially. The chief features in the farming system of France which strike an Englishman are the almost total absence of hedges, and the smallness of the farms or plots; the minute divisions of landed property having been long encouraged by the laws of France in every possible way. The end has been attained; considerable comfort has been diffused amidst the mass of the people, but with injurious results to agriculture. For in a country where the farms generally do not comprise more than from 15 to 20 acres, all the common evils of a land of small holdings are naturally felt. The capital required for them being limited, the competition to obtain them is naturally considerable; the charge for the labour to cultivate them is also great; the live stock kept on them inferior; the rotation of crops bad, and agricultural improvements of all kinds but slowly adopted. The government of France, it is true, in the absence of large landed proprietors, and opulent, enterprising, and scientific farmers, does all it can, by expensive state agricultural institutions, to supply their place; but these are not attended with the general advantages which are derived in other countries from the exertions of private individuals. Of these small farms, Mr. Denison has given the following graphic description (Journ. Roy. Agr. Soc. vol. i. p. 263):—"In comparison with the English system of enclosures, France may be called one vast open field; you may travel from Calais to Paris, from Paris to the German frontier, to the Alps, to the Pyrenees, and scarcely sees a hedge or a partition fence of any sort. This vast open field (unlike the open districts of England, where the operations of farming are generally conducted on the largest scale) is cut up into the smallest conceivable plots of every variety of produce. As far as the eye can reach, over vast plains bounded by sloping hills, you see the surface varied by every description of crop; none, perhaps, above an acre or two in size, the larger portion not more than the fourth or the eighth of an acre. Here a vineyard 100 yards by 20; there a strip of wheat, lucerne, barley, oats, potatoes, clover, and vetches. Few roads intersect this extensive garden, which, from the nature of the cultivation, must be traversed every day in all directions by the proprietors and cultivators of the various lots. The residences of these proprietors are almost invariably congregated into villages or towns, and lie, therefore, for the most part, wide of their respective allotments." The advocates of such a general system of cultivation will hence see that this mode of tillage is attended with sundry insupportable disadvantages. The public agricultural establishments maintained entirely by the French government are—1. Sheep farms; 2. Model farms; 3. Veterinary schools; 4. Haras, or studs. And it assists, by its patronage and with funds—1. Public lectures; 2. Agricultural societies; 3. Local associations; 4. Departmental model farms.

There are three public sheep farms; viz., at Rambouillet, Perpignan, and La Hayeveys.
France, Agriculture of.

At these, sheep are bred, and experiments in crossing bred. The chief breeds are the marne, the nax, a race with small frames and fine wool, and the English long-wooled sheep.

Of the model farms, Grignon, founded in 1829, and containing 1100 acres of land of different qualities, is the chief. It consists of arable, pasture, meadow, water meadow, and wood. Pupils are taken here, who pay in the house from 30l. to 60l. per annum, or, if they only attend the courses of instruction, from 8l. to 20l. The shortest course occupies two years; and after attending this period, and passing a public examination, the pupil may receive a diploma, taking rank as a sort of master of arts of Grignon.

The chief veterinary schools are at Alfort, near Paris, Toulouse, and Lyons. The three chief haras, or breeding studs, are at Dupin in Normandy (English blood horses), at Rozieres (a mixed breed called the "race ducale"), and at Pompadour (Arab and Persian). These contain together about 1500 horses. Of thorough-bred stock, in 1840, there had 167 stallions, 88 mares, and 111 colts and foals; for the use of the departments 870 stallions are kept at different stations. These are allowed the following amount of forage at three different stations:

<table>
<thead>
<tr>

The food of the small French Farmers, especially in Normandy, is very poor. "Many (says a writer in the Quart. Jour. of Agr. vol. xi. p. 2.) like the common labourers, live upon a few apples or pears, and a bit of bread, without the formality of sitting down to a table, and are content with a branch of their own home-made miserable cider." The breed of sheep is very inferior. Although many of the sheep are kept in flocks, yet there is little or no free range for them; they are usually kept in small lots of three or four, or half-a-dozen, and generally tied together by the legs. The average price of mutton is 3½d. per pound. Of the cattle, the Alderney blood seems to predominate. Bullocks are worked to a considerable extent, both in the plough and in the wagon. "Some centuries ago, Normandy was the source whence our Harems, and Edwards, and the flower of European chivalry, obtained their chargers; which were then a breed of large, powerful, active horses, able to bear the weight of an armed knight, with sufficient speed for the purposes of war. That breed has long since degenerated into an active and hardy horse, but totally devoid of those qualifications as to size and general appearance which we should think essential in a charger even for a common soldier; they seldom attain 15 hands in height, and are very short-necked, theirs rather large in the head, have good forelegs, but very imperfect in the hind ones, being too long from the hock to the hoof, and they are often diseased in those limbs from curb or sparvane, and deficient in width and muscle in the thigh. They have generally, however, good shoulders, back, and loins, many of them possessing very useful and short actions in the trot; and considered generally as a breed, they are able to go faster, and do more work than their appearance at first indicates: they are commonly worked at two years of age." With regard to the rotation of crops, there is little worthy of observation. In Normandy, a very common rotation is a three-shift of wheat, barley, clover, wheat; in others, a four-shift of potatoes, barley, clover, wheat. Their agricultural implements are few and defective. Dombasle's plough, modelled from that of Small's English plough, is the favourite plough in France; it has commonly, however, wheels added. The spade is employed to a considerable extent in the field culture of this great country, and the greatest portion of the country parishes of the nature of garden husbandry. The consumption of...
vegetables of all kinds is much greater in France than in England; and the same remark applies to bread, the price of which, in Paris, is regulated by the public authorities.

The care which is taken in France, by the government, to husband every particle of organic manure, is well worthy of the consideration of the public authorities in England, for nowhere is there a greater waste of the richest fertilizing matters than from the large cities and towns of England; a great and public loss, to which Dr. Erasmus Darwin has referred me to the Thames Improvement Company, thus alludes: "In no part of France, Wurttemberg, Bavaria, Bohemia, Prussia, Saxony, the Confederated States of Germany, Holland, and Belgium, is there a city in which, as in London, the general mass of filth, of every description, created by a vast population, is first allowed to enter the river which may happen to traverse that city, and is then returned, diluted with the water of that river, to the houses of the inhabitants, as is the case in London, to which it is used either for domestic or culinary purposes: although, by avoiding the latter disgusting alternative, foreign cities are less free from unpleasant smells than London is. In this respect it may be truly said, that foreigners smell the filth of their cities, but do not swallow it, whereas the Londoner swallows it, but seldom smells it."

In no large city of that part of Europe which I have recently visited, possessing a river, is any portion of the contents of cesspools and cesspools suffered to find its way, or to be emptied into it; except at Amsterdam, Antwerp, Brussels, Stuttgart, and Leipzig; and even there, only in a partial manner. In Paris the Seine is contaminated by one large drain only, conveying the urine from the large reservoirs of night-soil at Montfaucon, and by two smaller ones proceeding from cesspools. To convey generally, or to empty, even partially, any such matter into the river, is a practice against which the laws have provided by heavy fines and incarceration; and such is the present feeling of all the governments on that subject, even in France, that it is only on the banks of the Altamaha, in the state of Georgia, that it was discovered there in 1770, by John Bartram, who gave it its specific name. In height it rarely exceeds 30 feet, with a diameter of 6 or 8 inches. It blooms in Carolina about the beginning of July, and a month later near Philadelphia. The flowers are more than an inch in diameter, white, and of an agreeable odour. They have a slight resemblance to those of the dogwood (Cornus Florida). Like those of the Lobolly bay (Gordonia larsyathou), they open in succession during two or three months, and begin to appear when the tree is only 3 or 4 feet high. The fruit is in the form of round, lignonives capsules, which, when ripe, open at the summit in four seams to release the small angular seeds.

Although the Franklinia is found 2 or 3 degrees farther south than the Lobolly bay, it appears to be far less sensible to cold, and stands the climate well near Philadelphia, and will perhaps resist the winters higher north. (Michaux, "Genus," 54, 1790.)

FRENCH BEANS. See BEANS.

FRENCH CLOVER. See LUCERNE.

FREE-MARTIN. A name given by breeders to a twin cow calf born with a bull calf, which generally proves an hermaphrodite, and therefore barren; but in some cases, there not being this admixture of the organs of different sexes, or those of the female prevailing, she is capable of breeding. (Yonatt on Cattle, p. 539.)

FRINGE-TREE (Chionanthus Virginianus), a beautiful, small, American tree, abounding in the Southern States, and as high up as the vicinity of Dover, in the state of Delaware. It has been even met with on the banks of the Brandywine. The specific name is derived from its snow-white flowers, which are pendulous and fringe-like. There is another variety in the United States (the maritima of Pursh), which Lindley considers a distinct species. (Flor. Cestr.)

FROG OF A HORSE. In farriery, is a triangular portion of horn projecting from the sole almost on a level with the crust, and defending a soft and elastic substance called the
FROG-HOPPERS. The familiar name applied to singular insects (Ceropoditidea), which pass their whole lives on plants, upon the stems of which the eggs are deposited in autumn. “The following summer they are hatched, and the young immediately perforate the bark with their beaks, and begin to imbibe the sap. They take in such quantities of this, that it poizes out of their bodies continually, in the form of little bubbles, which soon completely cover up the insects. They thus remain entirely buried and concealed in large masses of foam, until they have completed their final transformation, on which account the names of cuckoo-spittle, frog-spittle, and frog-hoppers have been applied to them. We have,” says Dr. Harris, “several species of these frog-hoppers in Massachusetts, and the spittle, with which they are sheltered from the sun and air, may be seen in great abundance, during the summer, on the stems of our alders and willows. In the perfect state they are not thus protected, but are found on the plants, in the latter part of summer, fully grown, in upon large foam; “In this state they possess the power of leaping in a still more remarkable degree than the tree-hoppers: and, for this purpose, the tips of their hind shanks are surrounded with little spines, and the first two joints of their feet have a similar coronet of spines at their extremities. Their thorax narrows a little behind, and projects somewhat between the bases of the wing-covers; their bodies are rather short, and their wing-covers are almost horizontal and quite broad across the middle, which, with the shortness of their legs, gives them a squat appearance.”

FROGS (Rana, Linn.). The genus of amphi-ious reptiles, consisting of 17 species, but two only require to be here noticed:—

1. The Common Frog (R. temporaria), which is too well known to need description. Some of its properties are very singular, particularly its powers of leaping and swimming. Its body is naked, and without any tail; the fore limbs are very lightly made, while the hind legs and thighs are remarkably long, and furnished with strong muscles. As soon as the spawn is vivified, the future frog becomes a tadpole, in which state it is wholly a water animal, breathing by bronchia or gills, like a fish; but as soon as it is changed into a frog, and attains its proper shape, it acquires lungs, by which it breathes, and then immediately migrates to the shore.

2. The Gibbous, Green, or Edible frog (R. esculenta), which differs from the former species only in having a high protrubance in the middle of the back, which forms an acute angle. Its colours likewise are more vivid, and its marks more distinct, the ground colour being a pale or yellowish green, marked with rows of black spots from the head to the rump. The flesh of the hind thighs is used as a restorative food. The flesh of the Surinam frog (R. paradoxa) is also used as food. Frogs are recommended by Walton as bait for pike, but frogs retaliate by feeding on the spawn and young fry of fish in ponds and rivers.

FROST. Frosts are injurious to gardens and farms, the following view presented in a French periodical, is highly favourable to those much despised animals.

“Gardener’s wage the same war against frogs as with moles and all other insects mischievous to their crops. But they are wrong in including frogs in the general proscription, since they not only do them no injury, but render them, on the contrary, important services; for they are carnivorous as well as herbivorous, and greatly prefer insects to vegetable food. They are particularly fond of snails, and swallow them even with their shells on, when they are not too large. If you open a frog, you will find his stomach full of insects hurtful to agriculture, and especially snails. The shells they digest, or rather dissolve in their stomachs, in the same way that dogs do bones, and turkeys the shells of nuts.” (American Farmer.)

FROND. A combination of stem and leaf in one organ, as in ferns, Marchantia, and such like plants.

FROST. In meteorology is the cause of the congelation of water or the vapours of the atmosphere. When the air begins to freeze when the thermometer stands at 32°. At this temperature ice begins to appear, unless some circumstance, for example, the agitation of the water, prevents its formation. As the cold increases the frost becomes more intense, and liquids which resist the degree of cold required to congeal water at length pass into the solid state. When water remains at complete rest it may be cooled down to 28° Fahrenheit without freezing; but the moment it is agitated, the thermometer rises to 32° and the water freezes. In this case the insensible heat of the water is retained when the ice is formed, as the experiments have hitherto ascertained to what depth frost will extend, either in earth or water, but its effects will of course vary according to the degree of coldness in the air, the longer or shorter duration of the frost, the texture of the earth, the nature of the fluids with which the ground is impregnated, &c. In England the frost rarely extends in the ground below 18 inches from the surface. Frost is peculiarly destructive to vegetation. During severe frost almost all vegetables fall into a state of decay, and even a moderate degree of frost is sufficient to destroy many of the more tender kinds. The injury which vegetables sustain from frost is greatest when it is preceded by a thaw or copious rains; for the plants are then turgid with moisture, which, expanding in bulk as it passes into the solid state, produces the rupture of the vegetable fibres. Therefore it is that a sharp, north wind, or any thing which dries the sap or juices of vegetables previous to frost, tends to their preservation. The great power of frost on vegetables is well known. Trees are sometimes destroyed by it as if by fire, and split with a noise resembling the explosion of artillery, since the fibres of the tree expand with great force, as they are converted into ice. In winter, however, trees generally have neither leaves nor flowers, and their buds
are so hard as to withstand the effects of congelation; but hard frosts late in spring are often very injurious, as the buds are then appearing. Fruits are in like manner destroyed by frost. Their watery portion being changed into crystals of ice, occupying a greater space than the fluid from which they were produced, burst the small vessels in which they are formed; hence the fruit is deprived of its flavour, and when thawed putrefies.

The hoar-frost or white frost, which appears in the mornings chiefly in autumn and spring, is merely frozen dew. It is generally the consequence of a sudden clearing up of the weather after rain, when a considerable degree of cold is produced by the rapid evaporation. In northern climates, it usually happens that after a fall of rain the wind shifts into a northern quarter, and the atmosphere suddenly clears up. When this takes place during the night, or early in the morning, a strong radiation of heat from the earth commences, the cooling effect of which is increased by the copious evaporation from the wet surfaces of the plants and the grass. The influence of evaporation on the phenomenon is obvious from this, that the moisture which appears in the form of dew before sunrise, is often changed into rime, or hoarfrost, on the appearance of that luminary. The reason for this is, the atmosphere begins to be warmed by the sun's rays, the evaporation is accelerated, and consequently the cold at the wet surface of the ground augmented; hence, we see one reason why frosty nights are so much more prejudicial to the tender shoots of plants when they are succeeded by very bright mornings. Hence, also, hoarfrost is found on grass or plants, when the thermometer, placed a few feet above the ground, indicates a temperature three or four degrees above the freezing point.

In late autumnal frost, the effect of evaporation by the heat of the sun is often exemplified on the stems of potatoes. If a hoarfrost be immediately succeeded by the influence of the sun, the dew liquefies, and by the process of evaporation the stalks lose their vitality; for although plants, as well as animals, have an inherent power of resisting cold, yet it is in the former only to a very limited degree. If the hoarfrost be brushed off (and this can easily be done by two men moving along the beds or drills with a rope between them, very early in the morning, before the evaporation takes place), the stalks will sustain no injury. The destructive power of evaporation appears to be proportioned to the degree of humidity in the body on which it acts.

The following is recommended as a simple and easy method of securing fruit trees from the effects of frost:

If a thick rope be intermixed among the branches of a fruit tree in blossom, the end of which is directed downwards so as to terminate in a pail of water, should a slight frost take place during the night, it will prevent in the smallest degree affect the tree, while the surface of the pail which receives the rope will be covered with thin ice; though the water placed in another pail by the side of it, by way of experiment, may not, from the slightness of the frost, have any ice on it at all. In this case the rope aids the evaporation of the water, and thereby cools it down to the freezing point. Frost is merely the effect of cold, which, itself, is a mere negative quality; namely, the absence of heat. As evaporation carries off heat and reduces temperature, whatever aids this is favourable to freezing. (Quart. Journ. of Agr. vol. viii. p. 421.) Early hoarfrost may, it is said, be rendered harmless in its effects by pouring fresh spring water on the trees and vines thus covered before the sun rises. Various other projects have been proposed at different times to avert the disastrous effects of the morning frosts on vegetation in spring; but, unfortunately, it is only on a very limited scale that any means can be adopted for the purpose.

Whatever prevents the formation of dew will protect plants; hence a covering of net or thin gauze will often preserve the blossoms of wall-fruit. But the most effectual means is to check the radiation, by screening the plant from the chilling aspect of the clear sky. See Dew. Every farmer knows that frost in winter is serviceable to the soil, by breaking down and pulverizing land, and that a failure of crops frequently takes place after a winter of extreme mildness. The principle is this:—in the process of congelation, the water, as it freezes, expands, and separates, its vicinity is warmer, and the air is rendered a better source of life. In dry earth it has little or no effect in this way, but is beneficial in destroying grubs and insects. On sand it makes no impression. On ploughed clay-land frost has the most beneficial effect. Therefore, where the soil is close, stiff, or of an obstinate clayey nature, it should be turned up in ridges in the autumn or at the beginning of winter, which tends greatly to separate its particles, and render it more fine and mellow.

Hard winters seldom injure winter grain in any respect, especially where the land has been thoroughly drained, and is covered much with snow. By leaving the earth in a loose and finely divided state, frost adapts it better for the extension of the roots as the warmth of spring approaches, and thereby enables them to produce strong plants. (Brande's Dict. of Science.)

FRUIT (Fr. fruit; L. fructus; Span. fruta; Lat. fructum). In botany, comprehends many kinds of what are commonly called seeds; as those of corn, buckwheat, caraway, parsley, &c., as well as the succulent indolence of the pine-apple, which is a mass of ovaria and envelopes in a consolidated condition. But in horticulture the term fruit is restricted to the pulpy and juicy seeds of trees and shrubs, &c., as the apple, the peach, the currant, &c.

The fruits of vegetables are equally various with the seeds. They almost all contain an acid; and this acid is usually either the tartaric, the oxalic, the citric, or the malic, or a mixture of two or more of them. Hardly any other, excepted perhaps, the aspetic, has hitherto been found in fruits. They usually contain likewise a portion of saccharine gummy matter, sometimes starch; and the fleshy fruits

508
FRUIT-MAGGOTS.

contain also a fibrous matter, not yet accurately examined. The colouring matters of fruits, especially the red, dissolve freely both in water and alcohol, but very speedily decay when exposed dry to the action of the sun and weather. Hence they cannot be used as dyes.

The diseases of fruit-trees are various, and for these the reader is referred to the different heads of BLIGHT, CANKER, MILDEW, &c. As the culture and propagation of the different fruits are also treated of in separate articles, it will suffice in this place to enumerate a few of the principal works which may be consulted with advantage for fuller details than the limits of this work will enable me to give; among these are Hickey's Magaz. of Agriculture, &c.; Kenrick's Am. Orchardist; Hovey's Magaz. of Horticulture, &c.; Thatcher's Orchardist; New Magaz. of Gard.; London's Encyc. of Gard. &c.; Bliss's Fruit Grower's Instructor.

Several American works have been published of great value, upon the culture of fruit-trees, &c.; among these are included Core on Fruit-trees; Thatcher's American Orchardist; Hovey's Magaz. of Horticulture, &c.; Kenrick's Am. Orchardist; Fessenden's Am. Farmer and Gardener; Hovey's Orchardist's Companion, the last a splendid original work with plates.

FRUIT MAGGOTS. The little white maggots often found in our ripe whortleberries, raspberries, cherries, and other fruits, are the young of small two-winged flies, some of which family deposit their eggs in the stems, buds, and leaves of plants, thereby producing large tumors or galls wherein their young reside. The larve of those laying their eggs in fruit, live upon the pulp. The family of insects has received the name of Ortailidians, from a word signifying to shake or clap the wings; these being kept in motion all the time. Some of their larvae are well known and suddenly raising their wings perpendicularly above their backs, and running along a few steps with them spread like the tail of a peacock. Their powers of flight are feeble, and they are rarely found sporting on flowers in the sunshine, but generally prefer shady and damp places. The wings of the ortailidians are often beautifully variegated, striped or spotted, with shades of brown or black. (Harris.)

FRUIT-MOTH, or CODLING-MOTH. The insect, the eggs of which produce the well-known apple-worm, which has been brought from Europe to America, and naturalized wherever the apple tree has been introduced. This mischievous creature has sometimes been mistaken for the plum-weepil (see Curculio), but it may, says Dr. Harris, be easily distinguished from it by its shape, habits, and transformations. The plum-weepil is, however, sometimes found in apples; but the apple-worm has never yet been found in plums, so far as Dr. Harris has been able to learn. The apple-worm is not a grub, but a true caterpillar, the product of a moth, and not of a beetle, as grubs are. An anonymous writer in the Entomological Magazine of London, has well remarked of this moth (Carposcnpa pomenella), that "it is the most beautiful of the tribe to which it belongs; yet, from its habits not being known, it is seldom seen in the moth state; and the apple-grower knows no more than the man in the moon to what cause he is indebted for his basketfuls of worm-eaten windfalls in the stiller weather."

A good account of the apple-worm and its transformations, by Joseph Tufts, Esq., of Charleston, Massachusetts, was published in the Massachusetts Agr. Rep. and Journ., vol. v., and some remarks by Mr. Burrel, of Quincy, Massachusetts, may be found in the New England Farmer, vol. xviii. At various times between the middle of June and first of July, the apple-worm moths may be found in New England. "They are sometimes seen in houses in the evening, trying to get through the windows into the open air, having been brought in with fruit while they were in the caterpillar state. Their fore-wings, when seen at a distance, have somewhat the appearance of brown watered silk; when closely examined they will be found to be crossed by numerous gray and brown lines, scalloped like the plumage of a bird; and near the hind angle there is a large, oval, dark brown spot, the edges of which are of a bright copper color. The head and thorax are brown, mingled with gray; and the hind-wings and abdomen are light yellowish brown, with the lustre of satin. Its wings expand three-quarters of an inch. This insect is readily distinguished from other moths by the large, oval, brown spot, edged with copper colour, on the hinder margin of each of the fore-wings. During the latter part of June and the month of July, these fruit-moths fly about apple trees every evening, and lay their eggs on the young fruit. They do not puncture the apples, but they drop their eggs, one by one, in the eye or hollow at the blossom end of the fruit, where the skin is most tender. They seem also to seek for early fruit rather than for the late kinds, which we find are not so apt to be wormy as the thin-skinned summer apples. The eggs begin to hatch in a few days after they are laid, and the little apple-worms or caterpillars produced from them immediately burrow into the apples, making their way gradually from the eye towards the core. Commonly only one worm will be found in the same apple; and it is so small at first, that its presence can only be detected by the brownish powder it throws out in eating its way through the eye. The body of the young insect is of a whitish colour; its head is heart-shaped and black; the top of the first ring or collar and of the last ring is also black; and there are eight little blackish dots or warts, arranged in pairs, on each of the other rings. As it grows older its body becomes flesh-coloured; its head, the collar, and the top of the last ring, turn brown, and the dots are no longer to be seen. In the course of three weeks, or a little more, it comes to its full size, and meanwhile has burrowed to the core and through the apple in various directions. To get rid of the refuse fragments of its food, it gnaws a round hole out of the opening. Through this hole also the insect makes its escape after the apple falls to the ground; and the falling of the fruit is well known to be hastened by the injury it has..."
FRUIT-WEEVIL.

FUMITORY.

received within, which generally causes it to ripen before its time.

"Soon after the half-grown apples drop, and sometimes while they are still hanging, the worms leave them and creep into chinks in the bark of the trees or into other sheltered places, which they hollow out with their teeth to suit their shape. Here each one spins for itself a cocoon or silken case, as thin, delicate, and white as tissue paper. Some of the apple-worms, probably the earliest, are said by Kollar to change to chrysalids immediately after their cocoons are made, and in a few days more turn to moths, come out, and lay their eggs for a second generation of the worms; and hence much fruit will be found to be worm-eaten in the autumn. Most of the insects, however, remain in their cocoons through the winter, and are not changed to moths till the following summer. The chrysalid is of a bright mahogany-brown colour, and has, as usual, across each of the rings of its hind-body, two rows of prickles, by the help of which it forces its way through the cocoon before the moth comes forth.

"As the apple-worms instinctively leave the fruit soon after it falls from the trees, it will be proper to gather up all wind-fallen apples daily, and make such immediate use of them as will be sure to kill the insects, before they have time to escape. Mr. Burrell says that if any old cloth is wound around or hung in the crotches of the trees, the apple-worms will conceal themselves therein; and by this means thousands of them may be obtained and destroyed from the time when they first begin to leave the apples, until the fruit is gathered. By carefully scraping off the loose and rugged bark of the trees, in the spring, many chrysalids will be destroyed; and it has been said that the moths, when they are about laying their eggs, may be smothered or driven away, by the smoke of weeds burned under the trees. The worms, often found in summer pears, appear to be the same as those that affect apples, and are to be kept in check by the same means." (Harris)

FRUIT-WEEVIL. See CURCILLO; PLEXWEEVIL.

FUEL (Norm. Fr. fuage). Any combustible substance which is used for the production of heat constitutes a species of fuel; but the term is more properly limited to coal, coke, charcoal, wood, and a few other substances.

In England, coal, from its abundance and cheapness, is the commonly employed fuel; but where wood is abundant, or where its value is little more than that of selling it, it is used either in its original state, or in the form of charcoal. It is essential to good and profitable fuel that it should be free from moisture; for unless it be dry, much of the heat which it generates is consumed in converting its moisture into vapour; hence the superior value of old, dense, and dry wood, to that which is porous and damp. A pound of dry wood will, for instance, heat 35 pounds of water from 32° to 212°, and a pound of the same wood in a moist or fresh state will not heat more than 25 pounds from the same to the same temperature; the value, therefore, of different woods for fuel is nearly inversely as their moisture, and this may be roughly ascertained by finding how much a given weight of their shavings loses by drying them at 212°.

The following table exhibits at one view the power of various species of wood in producing heat.

The number indicates the quantity of timber in pounds, required to raise the temperature of a cubic foot of water from 52° to 212°.

The value of turf and peat, as fuel, is liable to much variation, and depends partly upon their density, and partly upon their freedom from earthy impurities. A pound of turf will heat about 26 pounds of water from 32° to 212°, and a pound of dense peat about 30 lbs. 1/2 compressing and drying peat its value as a fuel is greatly increased. Dr. McElloch has divided peat into five classes:—mountain peat, marsh peat, lake peat, forest peat, and marl peat; the names implying the locality of their production. Of these the mountain peat, from its loose, spongy texture, is the least productive of heat, although it soonest inflames. The reader is referred to an excellent essay "on economizing Fuel and Lighting," &c. by the Rev. P. Bell, in the Trans. of High. Soc. vol. iv. p. 149. See CHARCOAL and PEAT. (Brande’s Dict. of Science; Willich’s Dom. Encyc.)

FULLER’S THISTLE (Dipsacus fullonum). A name sometimes applied to a plant used by the makers of cloth. See TEASEL.

FULLER’S EARTH. A native saponeaceous mineral of the aluminous kind, found in many parts, but the best comes from the south of England and Saxony. It is much used by fullers in cleaning and scouring their cloth, from its property of absorbing grease. It is of a very soft, unctuous nature, falls to pieces in water, and appears to be capable of promoting the growth of plants in a high degree; consequently may be used with advantage as manure, on some of the lighter sorts of land. Its constituents, according to Klaproth, are as follows:—

FUMITORY (Fumaria, from famus, smoke, alluding to the disagreeable smell of the plant. Our English word fumitory is derived from the French name of the genus Fumellin). There are six indigenous species of fumitory, among which are:
FUNGI.

Common fumitory (F. officinalis), an annual, very common in cultivated ground and about hedges; root tapering, herb glaucous, stem much branched, leaves mostly alternate, twined or thrice pinnate. Flowers in clusters, rose-coloured or pale red. The leaves are succulent, saline, and bitter. The plant is eaten by cows and sheep; goats dislike it, except the young shoots, and horses totally refuse it.

Rampant fumitory (F. caperata). This species is much like the common fumitory, but larger are very rare part; the leaves less glaucous; their tendrils twisting round other plants, by which the branching stem climbs to the height of 3 or 4 feet. The flowers are on the whole paler, and the plant also less common. This species and the white climbing fumitory are the only ones worthy of extensive culture. They do best sown under a hedge, to which they will attach themselves and make a beautiful appearance. The common fumitory is the only species found in the United States, where it has been naturalized to some extent, being not infrequently cultivated in gardens. (Eng. Flor. vol. iii. p. 252-257; Paxton's Bot. Dict.)

FUNGLI, or FUNGUNGI. An African grain produced by a plant of Liliiformian growth, which is described by Mr. Clarke, in the proceedings of the London Linnean Society. This grain is represented as about the size of mignonette-seed, and is cultivated in the village of Kissy and in the neighbourhood of Waterloo by industrious individuals of the Scooso, Pontlah, Bassa, and Volpoff nations, by whom it is called "hungry rice." The ground is cleared for its reception by burning down the cope-scwood and hoeing between the roots and stumps. It is sown in the months of May and June, the ground being slightly opened and again lightly drawn together over the seed with a hoe. In August, when it shoots up, it is carefully weeded. It ripens in September, growing to the height of about 18 inches, and its stems, which are very slender, are then bent to the earth by the mere weight of the grain. The grains are reaped with hooked knives. The patch of land is then either suffered to lie fallow, or planted with yams or cassava in rotation. Manure is said to be unnecessary or even injurious, the plant delighting in light soils, and being raised even in rocky situations, which are most frequent in and about Kissy. When cut down it is tied up in small sheaves and placed in a dry situation within the hut, for if allowed to remain on the ground or to become wet the grains become aggutinated to their coverings. The grain is trodden out with the feet, and is then parched or dried in the sun to allow of the more easy removal of the chaff in the process of pounding, which is performed in wooden mortars. It is afterwards winnowed with a kind of cane funnel on mats.

In preparing this delicious grain for food, Mr. Clarke states that it is first thrown into boiling water, in which it is assiduously stirred for a few minutes. The water is then poured off, and the load add to it palm oil, butter, or milk; but the Europeans and negroes connected with the colony stew it with fowl, fish, mutton, adding a small piece of salt pork for the sake of flavour, and the dish thus prepared is stated to resemble kous-kous. The grain is also made into a pudding with the usual condiments, and eaten either hot or cold with milk; the Scotch residents sometimes dress it as milk-porridge. Mr. Clarke is of opinion that if the fundi grain were raised for exportation to Europe, it might prove a valuable addition to the list of light farinaceous articles of food in use among the delicate or convalescent.

Specimens of the grass have been examined by Mr. Kippist, Librarian to the Linnean Society. It is a slender grass with digitate spikes, which has much of the habit ofDigitaria, but which, on account of the absence of the small outer glumes existing in that genus, must be referred to Paspalum. Mr. Kippist regards it as an undescribed species, and distinguishes it by the name of Paspa-ulus excite. (Proceedings of Lin. Soc.)

FUNGI (Lat.). A large natural tribe of plants of a very extensive organization, consisting chiefly of cellular tissue, sometimes also of mucilaginous or flocculent matter, and very rarely furnished with spiral vessels. They form, as it were, a link between the animal and vegetable kingdoms. They inhabit dead and decaying organic bodies, and are also a common pest to living plants, upon which they are parasites, and prey in the same manner as vermin and intestinal worms upon animals. A vast number of species are described by writers upon fungi, and they are often of great importance to man, either for their use or their mischievous quality. The common mushrooms (Morchella.), the truffle (Tuber cibarius), and morel (Morcella esculenta), (see these heads) are delicacies well known at table. Not less than thirty-three species of fungi are eaten in Russia. Ergot, one of the tribe, is valuable in obstetric practice as a uterine stimulant; very many of the species are dangerous poisons. Blight, mildew, rust, etc. (see these articles), are diseases caused by the ravages of microscopic fungi; and, finally the destructive effects of dry-rot are owing to the attacks of Merulius lacrymans, and many other species. The best general work on fungi is Loudon's Fungi, or Puhgs Systema Mycologico. Numerous species are figured in the works of Greville, Bulliard, Sowerby, Corda, and Nees von Esenbeck. (See Faery Ring.) Dr. Christison gives the following general directions for distinguishing the esculent from the poisonous varieties. "It appears that most fungi which have aavy cap, more especially fragments of membrane adhering to their upper surface, are poisonous. Heavy fungi, which have an unpleasant odour, especially if they emerge from a vulva or bag, are also generally hurtful. Those which grow in woods and shady places are rarely esculent, but most are unwholesome; and if they are moist on the surface, they should be avoided. All those which grow in tufts or clusters from the trunks or stumps of trees ought likewise to be shunned. A mere test of a poisonous fungus is an astringent styptic taste, and perhaps also a disagreeable, but certainly a pungent odour. Those, the substance of which becomes blue soon after being cut, are invariably poisonous.

511
FURZE.

Agarics, of an orange or rose-red colour, and boleti, which are coriaceous or corky in texture, or which have a membranous collar around the stem, are also unsafe. These caution for knowing deleterious fungi seem to rest on fact and experience; but they will not enable the collector to recognise every poisonous species.” The general rules laid down for distinguishing wholesome fungi are not so well founded, but the most simple and easy mode of testing the quality of field fungi is to introduce a silver spoon or piece of coin of that metal, or an onion, into the vessel in which mushrooms are seething: if on taking either of these instruments, one does not feel black, dark discoloured appearance, there are certainly some dangerous fungi among them; if, on the other hand, the metal or onion, on being withdrawn from the liquor, wears its natural appearance, the fungi may be considered wholesome and innocuous. The symptoms indicating poisoning by fungi are nausea, vomiting, purging, and colic, in general accompanied with great depression of the pulse, cold extremities, clammy sweats, stupor, delirium, convulsions, sometimes paralysis. In such cases immediate means should be taken to clear the stomach, and a medical practitioner sent for, as the subsequent treatment must vary according to the symptoms in each individual instance. (Christian on Poisons; Brande’s Dict. of Science.)

FUNGUS. In farriery, a spongy excrescence which arises in wounds and ulcers, commonly known by the name of proud flesh. It may be destroyed and removed by caustic applications, such as nitrate of silver, or sulphate of copper, blue vitriol, and the use of tight bandages.

FURLONG (Sax. rup blasph). An English measure of length containing forty poles, the eighth part of a mile.

FURMEN'TY, or FRUMENTY (from frumentum, corn). A kind of country pottage prepared of wheat, which is first wetted, and beaten to deprive it of its husks, and afterwards boiled. When boiled up with milk, sugar, and a little spice, it forms a wholesome and agreeable food. This preparation was well known to the Roman farmers. Cato, the earliest of the agricultural writers whose works have escaped to us, gives (lib. lxxxvi.) the modern mode of making it under the name of wheat frumenty.

FURRIER’S REFUSE, or CLIPPINGS; are sometimes applied as a fertilizer to light chalks and gravelly soils, either ploughed in or laid upon the surface, in the proportion of twenty-four to thirty bushels to the acre. They are usually sold by the quarter, which commonly contains as much as two five-bushel sacks will hold when closely pressed. The price is said to be about 1½s. to 1½s. per quarter. (Brit. Hist. vol. i. p. 426.)

FURROW (Sax. pæh; Dan. fur; Lat. furus). In agriculture, a term not very properly defined, as it has three or four distinct significations; viz. 1. The soil turned up by the plough; 2. The trench left by this operation; 3. The interval between two ridges; and 4. The cross drain which receives the rain water collected by these intervals. Dr. Johnson adds a fifth; but he obviously mistakes furrow for drill. According to Mr. Marshall there are three kinds which lay claim to the word furrow. 1. The trench made by the plough, which may be called a plough furrow; 2. The collateral drains, or an inter-furrow; and 3. The transverse drains, or the cross-furrow. See Ploughing and Furrow, Water.

FURROW-SLICE. The narrow slice or slip of earth turned up by the plough. By the Scotch writers on husbandry, it is mostly termed fur-slice.

FURROW, WATER. That kind of deep, open furrow which is made by the plough in tillage-lands, for the purpose of draining off and draining them, in order to favour the healthy growth of the crops. Furrows of this kind should always be drawn in such directions as will most readily take off the water, and be kept open during the winter months, especially on the oat-grounds. The making of these furrow-drains should be performed immediately after the ploughing and sowing have been finished; and this is particularly necessary on all the more stiff and retentive kinds of soil.

FURZE, COMMON; GORSE, or WHIN (Ulex europaeus). Pl. 9. c. This hardy evergreen shrub is indigenous to most parts of Great Britain, and grows abundantly on sandy or gravelly heaths and commons; and when viewed in the light of a weed it is one of the most determined growers, and most difficult to get rid of that the agriculturist can meet with. The stem of the furze varies from 2 to 5 feet high; but in Cornwall and Durham it sometimes grows to the height of 8 or 9 feet. It bears innumerable dense, roughish, green, furrowed or ribbed branches, spinous at the ends, and beset with large, compound, striated, permanent thorns. The leaves are few, scattered, small, awl-shaped, deciduous. Flowers large, solitary or in pairs, of a bright golden yellow, with a very peculiar oppressive scent. One of our poets has well described the beautiful appearance of this shrub in blossom—

“...And what more noble than the vernal furze, With golden baskets hung! Approach it not, For every blossom has a troop of swords To defend it.”

The legumes are downy, bursting elastically in dry, hot weather, with a crackling noise, and scattering their seeds extensively. The wood of furze is very hard. Furze is chiefly used for fences, as food for cattle, and for fuel. Its preference for sterile soil has caused it to be extensively employed for fences in such land, and as a cover for game, and shelter for young plantations. With common care furze fences last for a very long period, but they require peculiar management to prevent the roots becoming exposed. Sowing in three tiers on a bank is perhaps the best mode, as it allows of one tier to be kept low by the shears or bill, the second of higher growth, and the last to attain its natural stature.

There are generally two objections advanced against the adoption of whin-fences. The first is, that the wall or mound required for raising the whin is of such dimensions as to occasion a great waste of ground; and the second is,
that the whins have a great tendency to spread over and injure the adjoining grounds. But with a slight, well trimmed wall-fence of furze these objections may easily be obviated.

The formation and management of whin-fences have been treated of by a number of writers, among them Lord Kames, Dr. Anderson, Marshall, Billington in his work On Planting, Dickson in his Modern Husbandry, and others; there is also an essay on this subject in the Trans. of the High. Soc. vol. v. p. 466, by Mr. W. Bell, and it is noticed in a number of the County Reports.

Furze has long been known as a plant highly nutritious as food for horses, sheep, and cattle, and has only been neglected from the supposed difficulty of converting it into a state fit to be comfortably eaten by domestic animals; the process of cutting, gathering, and bruising the young shoots, when taken from the old stunted bushes, being both laborious and expensive. These difficulties are, however, comparatively easily overcome when gorse is allowed the privilege of a cultivated spot, and the most worthless part of the farm is good enough for it to vegetate upon.

Respecting the merits of furze as a fodder, a good deal has been written, as by Duhamel in France, Evelyn in England, and Dr. Anderson in Scotland; and it is now extensively cultivated for this purpose by Mr. Attwood of Birmingham, who has devoted an hundred acres to French furze; (U. prorenialis, which is nearly allied to the common furze). These are regularly mown with a scythe for a corresponding number of milch cows, and bruised in a mill: mixed with chopped straw or hay, this constitutes the entire food of his cows. Bruised furze is also an excellent substitute for hay for horses, and it is even asserted that they prefer it to corn; but they should at the same time have oats and beans to counteract the relaxing properties of the gorse. Dr. Anderson says that when properly bruised, cattle are very fond of it, and increase in fatness as fast as on turnips. Cows yield as much milk as when fed on grass, without any bad taste, and the butter made on such food is very superior. The small holder bruises the furze for his solitary cow or pair of horses, in a trough, with a wooden pounder, furnished at the lower end with a sharp piece of iron. The farmer on a large scale should have a mill worked by horses or by water-power. In 1802 and 1803, the Duke of Richmond fed his deer, sheep, and horses extensively on whins. In the Peninsular war the forage consumed by the horses of the British army was principally furze. Mr. F. Tyler, in an account of experiments which he made on feeding horses, between the years 1812 and 1815 (Trans. High. Soc. vol. v.), states, that one of the chief kinds of food he used was furze. But the principal use of furze is for the purpose of fuel. In many parts of Great Britain it forms the main dependence for the supply of fuel for the poor man's hearth and the baker's oven. The common furze generally attains its full size in 4 years, and it ought not to be cut more frequently. An acre of land sown with the French furze will yield between 4 and 5000 fagots, which are chiefly consumed in the heating of ovens. The fresh and dried flowers of this plant afford dyeing a fine yellow colour. The medicinal qualities of furze are attenuant, diuretic, determining to the skin, and occasioning nausea. Furze may be propagated by seed sown from February to July. Young plants or cuttings planted in Spring or October will grow readily. It should be cut the year after sowing, beginning in September or October; it will grow again until Christmas, and be fit for use till March. Besides the common furze there are two other species:

1. The dwarf whin or furze (U. nanus) which is less common than the preceding, and only grows to half the size. It blossoms chiefly in autumn, has the leaves or spines shorter and closer, and the branches decumbent, the flowering ones more cylindrical and elongated; and the flowers are paler. These points of structure distinguish this species from the others at first sight. Its value is estimated in comparison to that of the common, as two to one inferior.

GAD-FLY, or BREEZE (Estrus equi et bovis, Lin.). Insects with spotted wings and a yellow breast, which have a long proboscis, with a sharp dart. These flies are particularly troublesome to cattle by their sting or dart. The horse-bot (Estrus equi) deposits its eggs on such parts of the horse as the animal can reach with his tongue. They are thus licked up, and introduced into the stomach; are there hatched and form bots. Another more tormenting fly of the same genus is the fundament-bot (E. hemorrhoidalis), which lays its eggs on the lips of the horse, causing so much irritation to the animal, as to induce him to gallop and seek refuge in the water. In Sweden, the grooms are accustomed to clean the mouths and throats of the horses daily with a peculiar kind of brush, which prevents the larvae of this insect getting into the stomach of the animal. The ox-warble (E. bovis) deposits its eggs on the back of oxen, causing great torture to the animal, and much agitation to the herd, if many are attacked at once. The ovipositor of the insect pierces the skin on the back of the ox, and there drops the eggs. At the season when the gad-fly infests them, the harness should be so managed as to allow the animals to be easily let loose. The ovipositor of the E. bovis is furnished with teeth, and acts like a sianug or gimen; and when this comes in contact with a nerve of sensation, the oxen seem to be driven almost to a state of madness; the tail is stretched out, and they gallop about the pasture, lowing and seeking for

513
GALLIC ACID.

water, into which they instinctively enter. Hence Virgil, describing this, says:

"The universal herbs in terror fly;
Their lowings shake the woods and shake the sky."

Humbold's mentions a species of Oestrus which is found in the low regions of the torrid zone, and has been named Oestrus hominis, from its attacking man, and depositing its eggs in his skin, causing there painful tumours. (La Géog. des Plantes, p. 186.)

Of the large God-flies, or Horse-flies found in America, one of the most common is of a black colour, having its back covered with a whitish dust, which, like a plum. The eyes are very large, and almost meet on the top of the head; they are of a shining purple-black or bronzed black colour, with a narrow, deep black band across the middle, and a broad band of the same hue on the lower part. The body of this fly is seven-eighths of an inch or more in length, and the wings expand nearly two inches. The Tabanum cinctus, of Fabricius, or orange-belted horse-fly, is not so common, and is rather smaller. It is also black, except the first three rings of the hind-body, which are orange-coloured. The most common of our smaller horse-flies is the Tabanum lineola, so named by Fabricius, because it has a whitish line along the top of the hind-body. Besides these flies, we have several more kinds of Tabanum, some of which do not appear to have been described. These blood-thirsty insects begin to appear towards the end of June, and continue through the summer, sorely tormenting both horses and cattle with their sharp bites. Their proboscis, though not usually very long, is armed with six stig, and exceedingly sharp needles, wherewith they easily pierce through the toughest hide. It is stated that they will not touch a horse whose back has been well washed with a strong decoction of walnut leaves. The eyes of these flies are very beautiful, and vary in their colours and markings in the different species.

The golden-eyed forest flies are also distinguished for the brilliancy of their spotted eyes, and for their clouded or banded wings. They are much smaller than the horse-flies, but resemble them in their habits. Some of them are entirely black (Chrysops ferrugatus, Fabricius), others are striped with black and yellow (Chrysops vittatus, Wiedemann). They frequent woods and thickets, in July and August. (Harris.)

GALLIC ACID. An acid obtained from galls and several other vegetable astringents, chiefly from the bark. The following table will serve to show the proportions of this acid in different plants:—

But although the above-named barks yield the quantities of gallic acid mentioned, yet it is uncertain whether they actually contain any ready formed. Gallic acid is procured by exposing the decoctions of galls, or of any astringent bark, to the air, until it becomes mouldy, and the tannic acid attracts the oxygen of the air, and is converted into the gallic acid. In this state the acid forms in crystals, mixed with crystals of another acid, the ellagic, which are easily separated from it, being insoluble in water.

Pure gallic acid has a weak, sour, astringent taste. It is soluble in 100 parts of cold water, and forms an ink with solution of green vitriol (sulphate of iron). It is distinguished from tannic acid, which is readily formed in astringent barks, by not precipitating solution of glue. It is a powerful astringent, and may be administered in doses of two or three grains in internal bleedings.

GALLINACEOUS FOWLS. One of the two divisions of domestic poultry reared in Europe, comprehend, among others, the common cock and hen, the turkey, the guinea-fowl, the peacock, and the pigeon.

GALL FLIES. See Fruut Faggots.

GALL NUTS (Fr. galle; It. galle). Excrecences produced by the Cynips, or Diplolepsis galle tinctoria, a small insect which deposits its eggs in the tender shoots of the Quercus infectio, a species of oak abundant in Asia Minor, &c. When the maggot is hatched, it feeds on the morbid excrecence formed by the irritation of the deposited ovum on the surrounding parts, and ultimately, when perfected as the fly, it eats its way out of the nidus thus formed. Good gall nuts are of a bluish-green hue, heavy, and break with a flinty fracture. When they are white, light, with a hole in one side, they are useless. Gall nuts are employed in dyeing, and in medicine.

GALLON. An English measure of capacity, containing 4 quarts. By act of parliament the imperial gallon is to contain 10 lbs. avoirdupois of distilled water weighed at the temperature of 62° Fahrenheit, and the barometer standing at 30 inches. This is equivalent to 277.274 cubic inches. The old English gallon, wine measure, contained 29 lbs. of cubic inches, and held 8 lbs. avoirdupois of pure water; ale and beer measure, 282 cubic inches, and held 10 lbs. 31 oz. avoirdupois of water; and the gallon for corn, meal, &c., 272 cubic inches, containing 9 lbs. 13 oz. of pure water. Hence the English imperial gallon is about 3 more than the old wine gallon, and about 2 less than the old ale gallon. See Weights and Measures.

GALLOP. In horsemanship, a well-known pace to which horses are trained, and of which many kinds are enumerated, but few only are worthy of regard, namely the hand gallop and the full gallop. And these distinctions are founded on the different degrees of velocity in which the animal is impelled, rather than on any peculiarity in the pace itself. In the gallop, the horse leads with one fore-leg somewhat advanced, but not so much beyond the other, as happens in the canter; and, when he is urged to his utmost speed, his legs are almost equally placed. The fleetest horses
when galloping, carry their bodies perfectly in a horizontal posture, and the fewer curves or successive arches are described, the more rapid of course is their progress.

In galloping, the fore-legs are thrown forward nearly simultaneously, and the hind-legs nearly to the rear and nearly together; it is, in fact, a succession of leaps, by far the greatest interval of time elapsing when the legs are extended after the leap is taken. The canter is to the gallop very much what the walk is to the trot, though probably a more artificial pace. The exertion is much less, the spring less distant, and the feet come to the ground in more regular succession. (The Horse, p. 413.)

GALLOWAY. The usual name for a poney or saddle-horse, between 13 or 14 hands in height. The original galloways are a pure breed of small, elegant horses from the south of Scotland, said to be of Spanish extraction. See Horse.

GALLOWAYS. See Cattle.

GALLS. In farriery, a term signifying an abrasion or rubbing off of the skin by the harness, saddle, &c. The little tumours resulting from the pressure of the saddle are called warts, and when they ulcerate they frequently become ulcers.

For saddle galls there is no better application than strong salt and water, mixed with a fourth part of tincture of myrrh. The saddle and the collar, when they are found to rub or gall, should be padded or chambered. A mixture of white-lead moistened with milk is stated (Quart. Journ. of Agr. vol. ix. p. 299.), to be an excellent liniment for galled backs in the early stages of the wound. It is a common remedy among American farmers.

For the information of other travellers, we may mention, says Mr. Keating, "that, after having tried many applications to the backs of horses when galled, we have found none that have succeeded so well as white-lead moistened with milk. When milk is not to be procured, oil may be substituted. Whenever the application was made in the early stage of the wound, we have found it to be very effectual; and it is likewise a convenient one, as two ounces of white-lead sufficed for the whole of our party for more than a month." (Expedition to St. Peter's River, p. 190.)

GALLS. In agriculture, a term signifying vacant or bare places in a crop.

GAMA GRASS (Tripsacum dactyloides), Finger-like Tripsacum, called also Sessame grass and Rough-seeded gama grass. (See Pl. 7, n.)

This stout and very remarkable grass has a perennial root. The culm rises to the height of 4, 5, or 6 feet, is somewhat compressed, channelled on one side, smooth, solid with pith, furnished with nodes or knots, smooth, slightly raised, with a dark-brown contracted ring. The leaves are large, often measuring 3 feet, and an inch to an inch and a half wide, smooth beneath, roughish on the upper surface, serrulate or finely jagged on the edges. Flower a dark purple; seed ovoid and smooth.

A few years ago," says Dr. Darlington, in his Flora Cestrica, "this grass was much exploited by some writers in the West, as an article of fodder for stock. The leaves and young plant may probably grow as well where they are wanted as where they are not; but when many in the West may soon satisfy himself that it can never supersede the good hay of this region (the Middle States), nor be as valuable in any respect as common Indian corn fodder." It is the only species of the genus Tripsacum which is indigenous in the United States, the T. monostachyum of some authors being only a variety. It has been found in Chester County, Pennsylvania.

From some communications in American periodicals, the gama grass appears to be particularly well adapted to Southern culture. It is exceedingly productive, being said to admit of at least six cuttings in a season, and to furnish a large quantity of palatable and nutritious food for cattle and horses. It is a hard perennial plant, and its duration, according to a Spanish proverb, coeval with the "age of a man and a mule." (Silk Culturist.) The modes of culture are by planting the seeds and transplanting the roots. Mr. Beekman, of Kinderhook, N. Y., gives the following directions: "Sow in drills 18 inches apart, and cover about 2 inches deep. In a month it will come up like oats, and when about 8 inches high and two suckers appear, one on each side, then transplant about 3 by 2 feet. The second year in Georgia the first cutting may be made in May, and once every month to 1st October, say six cuttings. The blades will be 3 feet or upwards—each forming a large bunch, which may be annually divided into from 40 to 50 plants.

The variety of gama grass so much vaunted in the Southern and Western States is said to be a hermaphrodite plant from the island of Jamaica, where it is extensively cultivated as a forage grass.

GARDENING. There is not in the arts and sciences one link of their circle so suitable for the occupation of man in a state of innocence, as that which embraces the cultivation of plants; and it is an instance of the beneficial providence of the Deity, that he assigned a garden as the dwelling of our first-created parents. It is no consequence of the fall of Adam that plants require cultivation: he was placed in Paradise to till and to keep it. Then the weed had not sprung up to render the tillage toilsome; fruit trees which God had planted were the chief objects of cultivation, and, if employment without much labour, combining the preservation of health with amusement, pure without insipidity, constant without sameness. From that period gardens have never ceased to engage the attention of man; and even now that their labours are manifold, they still afford the "purest of human pleasures."

To be an efficient cultivator of plants, a knowledge of botany is requisite. Whilist that science remained the chaos of unarranged facts, and ill-classified individuals, which was until the master-mind of Linnaeus reduced its confusion and discord to harmony in 1737, it required for its acquisition the devotion of a life. Such acquisition the new system of classi-
GARDENING.

The science of gardening, as it has been practiced in the past, is a rich tapestry of names and events. The term "botanist" has been synonymous with individuals who dedicated their lives to the study of plants, their cultivation, and the broader field of botany. Among these, Philip Miller, in his work, "The Four Books of Plants," compiled a list of over 1600 species. His Catalogus Plantarum Angliae, in 1670, contains 1050 species; his Synopsis, in 1696, describes more than 1600 species. A phalanx of botanists were then contemporaries who possessed the European gardeners of previous ages never equalled, nor succeeding ones surpassed. Ray, Tournefort, Plukenet, Commelin, Rivinus, Bobart, Petivir, Sherard, Boccone, Linneaus, may be said to have lived in the same age.

I will not pass unnoticed, as being of this period, Abraham Cowley, the well-known poet, physician, and author of "The Four Books of Plants." Although he deserves little praise as a botanist or as a gardener, he merits notice as assisting in their advancement, by writing to them and encouraging the attention of the literary. Of the influence which botanists possess over the forwarding the interests of horticulture, I shall quote but one more instance. Sir Arthur Rawdon was so gratified with the magnificent collection of West Indian plants possessed by Sir Hans Sloane, that he despatched a skilful gardener, James Harlow, to Jamaica, who brought there a vessel nearly freighted with vegetating and dried plants, the first of which Sir Arthur Rawdon cultivated in his own garden at Moira in Ireland, or distributed amongst his friends, and some of the continental gardens. His taste for exotic plants was probably much encouraged by his intimacy with Dr. William Sherard, who, being one of the most munificent patrons and cultivators of exotic botany during that "golden age" of the science, appeared, as Hasselquist observed, "the regent of the botanical garden" at his house at Sedekio, near Stuyrma, where he was British consul: for here he cultivated a very rich garden, and collected the most extensive herbarium that was ever formed by the exertions of an individual. It contained 12,000 species. His younger brother, Dr. James Sherard, also cultivated at Eltham, in Kent, one of the richest gardens England ever possessed. (Pultney's Sketches of Bot. vol. ii. p. 150.)

But it was not only in the collecting and arranging of plants that botany was adding fresh stores and zest to gardening. Previous to this period little was known of the structure of plants, and the uses of their several parts. Grew, Malpighi, Linneaus, Hales, Bonnet, Du Hamel, Hedwig, Spallanzani, &c., cleared away, in a great measure, the ignorance which enveloped vegetable physiology. Previous to their days the male bearing plants of dicotyledonous plants, as spinach, and the male flowers of cucumbers, &c., were recommended to be removed as useless; they taught the importance of checking the return of the sap; the mode of raising varieties; in short, all the phenomena of vegetable life, which throw so much light upon the practice of the gardener, were first noted and explained by the labours of these philosophers. Another class of philosophers who contributed a gigantic aid to the advancement of horticulture, were those chemists who especially devoted themselves to the vegetable world. Such men were Ingenhouz, Van Helmont, Priestley, Senebier, Schraeder, Suassure, &c. To them we are indebted for the most continuous research into the food of plants, the influence of air, of heat, of light, and of soils. Previous to their researches the immense importance of the leaves of plants was unknown. Cultivators were unaware that by removing one of them they were proportionately removing the means of breathing and of nourishment from the parent plant; and mankind in general were ignorant that it is by the gas which plants throw off that the animal creation is alone enabled to breathe.

The scientific institutions of previous years, which had merely existed, were now in a state of vigorous action. The Botanic Gardens at Chelsea was especially distinguished under its curator Philip Miller. This garden, as previously stated, was founded in 1673, though the inscription over the gateway is dated 1686, until which year it was not effectually arranged. It was strengthened and rendered permanent by Sir Hans Sloane, in 1721. He, having purchased the manor, gave the site, which is a freehold of four acres, to the company, on condition that they should pay 56 per annum for it, and that the company, in their name, should deliver annually 50 new species of plants to the Royal Society, until the number amounted to 2,000. This presentation of plants commenced in 1722, and continued until 1773, at which time they had presented 2550 species.

If old botanical institutions improved, so also new ones were formed. The Kew Gardens were commenced in 1760, by the Princess Dowager of Wales, mother of George III. The exotic department was established chiefly through the influence of the Marquis of Bute, a great patron of gardening. It was placed under the care of Mr. W. Aiton, and it has since become one of the most celebrated botanical institutions in the world.

The Cambridge Botanical Garden was also founded in 1763, by Dr. Walker, vice-master of Trinity College. He gave the site, comprising nearly five acres, in trust to the chancellor, masters, and scholars of the university, for the purpose of establishing the garden. Thomas Martyn, the titular professor of botany, was appointed reader on plants, and Charles, son of the celebrated Philip Miller (who had
Aided Dr. Walker in selecting the ground); was made first curator. (Loudon's Encyc. of Gard., pp. 86, 1071, ed. 4th.) Previous to this period, the number of exotics cultivated in England probably did not exceed 1000 species; during this century above 5000 new ones were introduced. Some tolerably correct ideas may have formed of the improvement arising to horticulture, from this spirit of research after plants, by a knowledge that in the first edition of Miller's Dictionary, in 1724, but 12 evergreens are mentioned. The Christmas flower and aconite were rare, and only to be purchased at Mr. Fairchild's nursery at Hoxton. Only seven species of geranium were then known. In the preface to the eighth edition of the Dictionary, in 1768, the number of plants cultivated in England are stated to be more than double those which were known in 1731. The publication of the seventh edition of that work, in 1759, was of the greatest benefit to horticulture. In it was adopted the classical system of Linneus. It gave a final blow to the invidious line of distinction which had existed between the gardener and the botanist, and completed the erection of the art of the former into a science, which it had been long customary to esteem little more than a superior pursuit for a rustic. From being merely practised by servants, it became more extensively the study and the delight of many of the most scientific and noble individuals of England. Miller improved the cultivation of the vine and the fig, and was otherwise distinguished for his improvement of the practice, as he had been of the science, of gardening. Having thus decisively gained the attention of men of science, the rapid progress of horticulture from this era is no longer astonishing. The botanist applied his researches to the increase of the inhabitants of the garden, and the better explanation of their habits. The vegetable physiologist adapted his discoveries to practical purposes, by pointing out the organs and functions which are of primary importance; and the chemist, by his analysis, discovered their constituents, and was consequently enabled to point out improvements which practice could only have stumbled on by chance, and perhaps during a lapse of ages.

The general introduction of forcing houses likewise gave to our science a new feature. Green-houses, we have seen, were in use in the 17th century; but no regular structures, roofed with glass, and artificially heated, existed until the early part of the succeeding one. Though a pine-apple had been presented by his gardener to Charles II., it is certain that they were only successfully cultivated here about 1723, by Mr. Henry Talende, gardener to Sir Matthew Decker at Richmond; Mr. Loudon gives the date as 1718. Mr. Bradley says, that Mr. Talende, thus striking length, succeeded in ripening them, and rendered their culture "easy and intelligible," he hopes bananas may flourish for the future in many of our English gardens.

(Bradley's Gen. Treatise on Husb. and Gard.)

That forcing was rare, and but of late introduction, is further proved by Mr. Lawrence, who, in 1718, observes, that he had heard that the Duke of Rutland, at Belvoir Castle in Lincolnshire, had planted his garden in 1685, burning from Lady-day to Michaelmas behind his sloped walls, a report to which he evidently does not give implicit credence, but which "it is easy to conceive." (Lawrence's Fruist Gard. Cat. p. 22.) That such, however, was the fact, is confirmed by Switzer, who further adds, in 1724, that they were covered with glass. The walls were erected, he says, at the suggestion of Mr. Facio, whom we have before mentioned. The walls failing in their anticipated effect were covered with glass, and thus led to the first erection of a regular forcing structure of which we have any account. (Switzer's Practical Fruit Garden, p. 318.) Lady Wortley Montagu, in 1716, mentions having partaken of pine-apples at the table of the elector of Hanover; and speaks of them as being a thing she had never seen before, which, as her ladyship moved in the highest English circles, she must, had they been introduced to table here.

Mr. Fowler, gardener to Sir N. Gould at Stoke Newington, was the first to raise cucumbers in autumn, for fruiting about Christmas. He presented the king, George I., with a brace of full-grown ones on new year's day, 1721. (Bradley's General Treatise on Husb. and Gard. vol. ii. p. 61.)

Even as late as the commencement of the century we are tracing, every garden vegetable, in a greater or less degree, was obtained from Holland. The purveyors of the royal family sent thither for fruits and pot-herbs; and the seedsmen obtained from thence all their seeds. But in 1727, Switzer boasts of the improvements made in his art. Cucumbers, that 25 years before were never seen at table until the close of May, were then always ready in the first days of March, or earlier if tried for. Melons were improved both in quality and earliness. "The first, owing to the correspondence that our nobility and gentry have abroad, now equaling, if not excelling, the French and Dutch in their curious collections of seed; but the second is owing to the industry and skill of our kitchen gardeners." Melons were now cut at the end of April, which before were rare in the middle of June. The season of the cauliflower being in perfection was prolonged from three or four, to six or seven months. Kidney-beans were now forced. The season of peas and beans was extended to a period from April until December, which previously only lasted two or three months, &c. (Preface to Switzer's Fruist. Fruit Gard.)

The early part of this century witnessed the labours of Professor Bradley, who was one of the first to treat of gardening and agriculture as sciences. Although deficient in discoveries, his works are not destitute of information derived from contemporary gardeners and other writers. He wrote lucidly on his subjects, and especially on the mode of obtaining variegated plants and double flowers. He must be looked upon as a benefactor of horticulture, for he at least made himself acquainted with the discoveries of others, and, recording them in his widely-circulated works,
he spread such increased knowledge, and diffused over the whole such philosophic views, as the science of the age afforded.

Some of our most celebrated nurserymen flourished during this century. Fairchild, Gordon, Lee, and Gray introduced many plants during its first half. Hibbert of Chalfont, and Thornton of Clapham, deserve particular mention for their encouragement of exotic botany. The garden and hothouse of the latter were among the best stocked about London.

We have seen under what favourable auspices and with what great improvements gardening was on the advance at the close of the 18th century; but the present century was ushered in with even greater promise of success, for the light of science was still more powerfully concentrated upon its practice, and began to be felt and appreciated. This especially applies to the labours of the chemist and physiologist. Such combination of horticultural art and science was especially promoted by the institution of the Horticultural Societies of London and Edinburgh. The first of these societies began to be formed in 1804, the latter in 1809. Nothing can more conspicuously display the high estimation in which gardening is held, nothing can afford a greater guarantee for its improvement, than the lists of the fellows of the above societies. In them are enrolled the names of the most talented, the most noble, and the most wealthy individuals of the United Kingdom.

The increase of inhabitants of our pleasure grounds within the last few years places the taste and patronage which are bestowed on gardening in a very conspicuous point of view. Of store plants we now cultivate about 1800 species and varieties. Of green-house plants, nearly 3600. Of hardy trees and shrubs, nearly 4000. Of hardy perennial flowers, nearly 3000. Of biennial and annual flowers together, about 800. To particularize the different genera of these would exceed the limits I have prescribed to this article. I have not included the varieties of florist's flowers in the above general list, for they are more than proportionately numerous. Of hyacinths we have about 300 varieties, whereas in 1629 Parkinson mentions but 50. The passion for this flower, however, has much abated; for Miller, in the early part of the last century, says the Dutch gardeners had 2000 sorts. Of tulips, we have nearly 700 varieties. The cultivation of this flower has also declined of late years. It was at its height both in England and in Holland towards the middle of the 17th century. In Holland nearly 6000, was agreed to be given for a single root. Of the ranunculus we have nearly 500 varieties. Of the anemone, about 200. Of dahlias, between 200 and 300; narcissi, 200; auriculas, more than 400; pinks, 300; carnations, about 350. Of roses, included in the list we have given of hardy trees and shrubs, there are more than 1450. Another instance of the progress made in increasing the number of our cultivated plants is furnished by the genus Erica. But five kinds of heath were described by Miller, as known in England about 60 years since; we now cultivate nearly 350.

Mr. Loudon makes the number of plants cultivated by gardeners at present amount to 13,140. Of these 1400 are natives of Great Britain; 47 were exotics introduced previous to and during the reign of Henry VIII.; 7 during that of Edward VI.; 533 during that of Elizabeth. In that of James I., 20. Charles I., 331. During the usurpation, 95. Charles II., 153. James II., 44. William and Mary, 298. Anne, 201. George I., 152. George II., 1770. George III., 6756. During the first 16 years of this century, on an average, 156 plants were annually introduced. The ardour of research is not the least abated now.

The style in which grounds in England are now usually laid out may be characterized in one sentence. Convenience is endeavoured to be rendered as attractive as possible, by combining it with the beautiful and appropriate. The convenience of the inmates of the mansion is studied by having the kitchen and fruit gardens near the hothouse fully extended enough to supply all their wants, and kept in the special beauty of order and neatness; without any extravagant attempt at ornament by the mangle of useless trees, or planting its cabbages, &c., in waving lines. In the flower garden which immediately adjoins the house, dry walks—shady ones for summer, and sheltered, sun-gladdened ones for the more temperate seasons—are conveniently constructed. Their accompanying borders and parterres, are in forms, such as are most graceful, whilst their inhabitants, distinguished for their fragrance, are most happily blended in grassland to his cottage; and those noted for their elegant shapes and beautiful tints are grouped and blended as the taste of the painter and the harmony of colours dictate. The lawn from these glides insensibly into the more distant ground occupied by the shrubberies and the park. Here the genius of the place dictates the arrangement of the levels and of the masses of trees and water. Common sense is followed in planting such trees only as are suited to the soil. A knowledge of the tints of their foliage guides the land scape gardener in associating them; and aids the laws of perspective in lengthening his distant sweeps. If gentle undulations mark the surface, he leads water among their subdued diversities, and blends his trees in softened groups, so as to form light glades to harmonize with the other parts. If high and broken ground has to be adorned, the designer mingles waterfalls with broader masses of darker foliated trees, and acquires the beauty peculiar to the abrupt and the grand, as in the former he aimed at that which is secured by softer features.

He is no philosopher who neglects a certain present good for fear that in some future period it may be abused; but in the encouragement of gardening, whilst an immediate good is obtained, there is no fear of its perversion in after days. Its diffusion among the poorer classes is an earnest or means of more important benefits, even than the present increase of their comfort. The labourer who possesses and delights in the garden approach to his cottage is generally among the most decent of his class; he is seldom a frequenter of the ale-
GARLIC.

GARLIC. 

Great, stem and pure, appetite. On hanging mankind greatly the door, in which it can win no attention, or to which it can afford no pleasure. He who greatly benefited or promoted the happiness of mankind in the days of paganism was invoked after death and worshipped as a deity; in these days we should be as grateful as they were without being as extravagant in its demonstration; and if so, we should indeed highly estimate those who have been the improvers of our horticulture; for, as Socrates says, "it is the source of health, strength, plenty, riches, and honest pleasures." "It is the purest of human pleasures," says Lord verulam. It is amid its scenes and pursuits that "life flies pure, the heart more calmly beats." (G. W. Johnson's History of Gardening."

GARLIC. In farriery, a disease in the ud- ders of cows, arising from inflammation of the lymphatic glands. It is also a distemper incident to hogs; and which is known by their hanging down their heads, and carrying them on one side, moist eyes, staggering, and loss of appetite.

In order to remove the disease in cows, where the inflammation is great, the cow should be bled, a dose of physic administered, the udder well fomented, and the milk drawn gently but completely off, at least twice a day. (Youatt on Cattle, p. 553.) When the disease happens to hogs, they may also be bled, and should have warm, stimulating cordial drinks.

GARLIC (Allium, from the Celt.; all, hot or burning). Under this name Sir J. Smith, (Eng. Flor. vol. ii. p. 139) enumerates seven native species:

1. The great rounded-headed garlic, (A. angelo- praorum). A rare plant, found occasionally in open hilly places. The stem is two or three feet high, and the herbage somewhat similar to that of the leek; the white globose bulbs or cloves increase rapidly in a garden, by lateral offsets, till they compose a mass as big as a man's head, resembling a bunch of grapes. The scent of the whole plant is strong, and of the most disagreeable kind.

2. The sand garlic (A. aremarum), found in mountainous woods and fields in the north, on a sandy soil; stem two or three feet high, bulbs small, ovate, with many purplish offsets.

3. The mountain garlic (A. carinatum) which is nearly related to the next following species, though differing in the flatter form of its leaves.

4. The streaked field or wild garlic (A. olera- ceum) found in pastures, meadows, corn fields, and their borders—producing whitish green blossoms in July. The whole plant has an unpleasant scent of garlic, and is a very troublesome weed, difficult of extirpation, though not of common occurrence. It is eaten by cattle, sheep, and hogs, and the tender leaves, boiled in soups, or fried with other herbs, form a wholesome article of food.

5. The crow garlic (A. vinaceum) which grows in dry pastures, corn fields, and waste ground among ruins, especially on a chalky or gravelly soil. The stem is slender, about two feet high, bulb small, ovate, white, flowers small, pale rose-coloured.

The species of garlic has generally been considered perennial, but Dr. Darlington regards the common garlic of our American fields as biennial, propagated every year by new lateral bulbs, the old ones, after once sending up a stem and flowering, dying away. This species is a foreigner, and has been extensively naturalized in the United States, constituting in many places a great nuisance, not only by imparting a disgusting flavour to milk, butter, cheese, &c., but seriously injuring flour, and rendering its manufacture difficult. Farmers are however able to subdue it by a judicious rotation of crops. The oat and other spring crops, are highly instrumental in the destruction of garlic.

The species called meadow garlic (Allium Canadense), is found in the Middle States, being frequent on the banks of the Brandywine, in which last mentioned locality the three-borried or three-seeded garlic, is also met with. The bulbs of this last are of an oblong oval shape, pointed, and rather large. The leaves are 5 to 8 inches long, and 1 to 2 inches wide, tapering to the base. This species, says Dr. Darlington, differs remarkably from all other alliums found in the United States, and has much resemblance to the A. ursinum, of Europe. The large leaves die, and disappear, early in the season—before the flowers are developed. The bulbs emit a fetid, disagreeable odour, whilst drying. Three or four additional species of garlic are found in the United States. (Flor. Cestrica.)

6. The broad-leaved garlic or ramsone (A. ursinum), which grows in moist woods, hedges, and meadows, and produces large white flowers, that blow in the month of May and June. Every part of the plant, when trodden upon, or otherwise bruised, exhales the strong odour of its genus. This species is eaten by cows; but if they feed on it ever so sparingly, it communicates its nauseous flavour to the milk and butter to such a degree as to render those articles offensive during the spring. It should therefore be carefully eradicated as an intolerable nuisance from all pastures. It affords an excellent remedy for driving away rats and moles, and it is said the plant will not suffer any other vegetable to thrive near it.

7. Chic garlic (A. schiovoprasum), which is rare, but sometimes found in meadows and pastures, and was formerly in great request as an ingredient in salads, but has been latterly neglected.

The cultivated varieties are—Common garlic (A. sativum), which is a hardy plant, and though generally known in the United States by the name of English garlic, it is a native of Sicily, capable of growing in almost any soil.
It is generally propagated by the cloves obtained by parting the root, but may be raised from the bulbs produced on the stem. The planting may be performed any time in February, March, and early in April, but the middle of the second is the usual time of insertion. A single clove to be placed in each one of holes made 6 inches apart and \( \frac{1}{2} \) deep, in straight lines, 6 inches distant from each other, care being taken to set the root end downwards; to do this with the greatest facility, it is the best practice to thrust the finger into the bulb, holding a clove between them, to the requisite depth, without any previous hole being made.

The only cultivation required is to keep them clean of weeds, and in June the leaves to be tied in knots, to prevent their running to seed, which would greatly diminish the size of the bulbs. A few roots may be taken up as required in June and July, but the whole must not be lifted until the leaves wither, which occurs at the close of July, or in the course of August. It is usual to have a part of the stalk attached, by which they are tied into bundles, being previously well dried by exposure to the sun and air, for keeping during the winter.

Rochambole, or, as it is sometimes called Spanish garlic (\textit{A. scorodoprasum}), has its bulbs or cloves growing in a cluster, forming a kind of compound root. The stem bears many bulbs at its summit, which, as well as those of the root, are often preferred in cooking to garlic, being of much milder flavour. It is best propagated by the root bulbs; those of the stem being slower in production. The plantation may be made either in February, March, or early part of April, as well as throughout the autumn. They may be inserted either in drills or by the dibble, in rows 6 inches apart each way, and usually 2 inches within the ground, though this, as well as the preceding variety, would thrive better if grown on the surface. A very small bed is sufficient for the supply of the largest family. See \textit{Shalot} and \textit{Lake}

Besides the above, there are large numbers of different species, most of which are very: they increase abundantly from offsets. The onion, leek, garlic, shalot, chives, &c., all agree in their stimulant, diuretic, and expectorant effects, differing in degree of activity. See \textit{Onion}.

\textbf{GARNER.} A term used provincially to signify a granary, or repository for corn; also a binn or a mill. See \textit{Granary}.

\textbf{GAS, AMMONIACAL.} See \textit{Saline Substances}; their uses to vegetation.

\textbf{GASES.} \textit{Their uses to vegetation.} It is not, I think, necessary, in drawing the cultivator's attention to the uses of that great portion of the food of plants which they imbibe in the state of gas, or of aqueous vapour, to enlarge upon the importance of the question, since that is a truth which, as illustrating the value of certain modes of cultivation, I hope to render intelligible in the following paper, as I examine in succession the advantages of the gases and vapour of the atmosphere, as well as those emitted during putrefaction, to the commonly cultivated crops of the farmer. And even if the accomplished farmer shall dissent from some or all of my conclusions, he will yet readily admit that all such observations, with regard to the habits and food of plants, and their ready absorption by the soil, cannot be too generally understood and acted upon by the cultivators of the soil.

That the atmospheric air exerts an extensive and very important influence upon vegetation, is a fact which has been well known from the earliest times, and widely observed by the earliest farmers. Too many circumstances combine to render this truth apparent to the very meanest cultivator for it long to escape observation. The superior luxuriance of the \textit{borders} of all growing crops, from those of the field to the outer circle of timber in a wood, naturally pointed out that \textit{something} was gained by these, of which the inner sheltered portions were partially deprived. And that this something was the air of the atmosphere, appears to have been the conclusion of the early Roman agriculturists, who, in all ancient ages, were attentive to let their crops enjoy as much of the breeze as possible; an object which they endeavoured to attain, not only by an attentive consideration of the natural and acquired habits of the plants in transplanting them, but also by increasing the access of air to their roots by deep and regular periodical stirrings of the soil around them. Thus Cato, the earliest of their agricultural writers, whose works remain to us, when instructing the Roman farmers as to the best mode of cultivating the vine and the olive, advised them, if they wished their vines and olive-trees to grow luxuriantly, to stir the trenches around them once a month, until they were three years old; and he adds, "bestow the same care upon other trees." (lib. xiii.)

And Virgil, when commending the very doubtful plan of paring and burning lands, alludes to the same well-known advantage of a free and copious supply of air to the roots of plants, when he says, "the heat opens more ways and hidden rents for the air, through which the dewers descend to the day's plants," (\textit{agrine homine semper cuncta}, i. 90, 91.) They, in fact, considered, in common with the Greek philosophers, that air was one of the four elements of which all substances were composed; but then, as in those days, the air of the atmosphere was considered to be a simple body, we need not search in the works of the early agricultural writers for any evidence of very definite ideas of the mode of its action. That the air they breathed was highly serviceable to plants of all kinds was the extent of their information; they had no knowledge of the existence of three distinct gases in the atmosphere. That was a discovery reserved for modern ages—for the days of Priestley, and the dawn of pneumatic chemistry in England. When, therefore, the early cultivators made the observation, that the free supply of air to the leaves and roots of plants materially promoted their growth, they did what too many modern agriculturists have since done, merely noticed the effect, without making any very accurate inquiries as to the cause of the benefit; they were too often content, in fact, with merely substituting words as
GASES.

an explanation of facts. It is probable that the early Greek and Italian philosophers were farther led to this knowledge of the advantages of air to vegetation, from noticing the power which some eastern plants, formerly known to philosophers, of entirely supporting themselves upon the nourishment they derive from the atmosphere, even when suspended by a string from the ceiling of a room,—many parasitical plants subsist upon hardly any thing else; thus, some of the mosses of this country cling to life, and even grow well, in situations where hardly any thing except air and moisture can nourish them; some of the aloe tribe do the same.

Carbonic acid gas. When, however, later ages had acquired the knowledge that it was only a portion of the air that maintained vegetable and animal life, or supported combustion, new views opened upon the chemical philosopher. It became then a question of considerable interest to ascertain which portion of the atmosphere it was that the plant absorbed; and it was speedily ascertained by Dr. Priestley and other chemists, that the portion of the atmosphere which the leaves of all plants absorb in the light is the carbonic acid gas or fixed air—a gas composed of 27-27 parts carbon, and 72-73 parts oxygen,—and that this carbonic acid gas is always contained in the atmosphere, in the proportion of about one part in 500. The question thus became one of some interest to ascertain, whether a larger volume of carbonic acid gas would promote, in a still greater degree, the growth of plants, such as in an impure, confined portion of air spoiled by the breathing of animals, or exhausted of its oxygen gas or vital air by combustion, since both these varieties of air contain a very considerably increased proportion of carbonic acid gas. Many very accurate experiments speedily demonstrated that such foul air materially increased the luxuriance of vegetables confined in them, and that plants possessed also the power of restoring to such exhausted air the portion of oxygen which either fire or the breathing of animals had removed: thus, a confined portion of air, in which a mouse had died in ten minutes for want of air, having had a sprig of mint introduced into it for some hours, was then found to be so replenished with vital air, that a second mouse being placed in it lived as long as the former mouse; and, by similar treatments, a lighted taper being merely substituted for the mouse, the same effect was produced—the exhausted air was again replenished with oxygen gas.

These facts naturally opened new views. It then became an interesting object to ascertain the proportion of the carbonic acid gas in the atmospheric air, which possessed the maximal advantage to vegetation; and it was found that, in pure carbonic gas, plants would not vegetate at all, or in air containing 75 per cent. of it, but that, when the proportion present in common air was reduced to 50 per cent., then the plants confined in it slowly vegetated, and that they grew more freely when the proportion was 25 per cent.; still better when it was 12½ per cent.; and that when it was reduced to only 9 per cent., then they flourished much better than in common atmospheric air.

GASES.

It was remarked, however, that the increased presence of carbonic acid gas was only beneficial to plants when they were vegetating in the light, but that, when this was excluded, the carbonic acid gas was rather prejudicial to their growth than otherwise; that, in fact, all plants, though they absorb it in the light, yet in the dark emit this gas. It was ascertained, however, that the presence of it in their atmosphere was absolutely essential to all plants vegetating in the light; that they grew when it was present, and that all vegetation was stopped by its withdrawal.

These results naturally led to the additional inquiry, whether the presence of carbonic acid gas in water produced the same results on plants, since it was well known that, when plants were immersed in water and exposed to the sun's rays, they emitted bubbles of oxygen gas, by decomposing the carbonic acid gas, and setting its oxygen free. Various kinds of water were tried, containing different proportions of carbonic acid gas; and the beneficial result upon vegetation was found to be exactly proportionate to the quantity of carbonic acid gas which they contained. In pump-water, they yielded the most oxygen: from river water a smaller quantity; but from boiled water little or none. Now, by boiling, all the gases are driven out of water, and this is the reason why such water is flat and insipid. And yet it was found that when the boiled water was again impregnated with carbonic acid gas, those plants confined in it emitted as much oxygen gas as they did before it was boiled; and, finally, that when the plants had exhausted the water of carbonic acid gas, then they ceased to emit oxygen.

The quantity of carbonic acid gas which is emitted by plants varies in different species. Thus, M. Saussure found that the purple loose-strife (Lythrum salicaria) absorbed in 12 hours 7 or 8 times its bulk; while the Cactus opuntia, in common with other fleshy-leaved plants, did not absorb above one-fifth of that amount. In these experiments, however, the atmosphere in which the plants were confined contained 7½ per cent. of this gas; so that when they are vegetating in the open atmosphere, in which the proportion of this gas does not exceed one part in 1000, the quantity absorbed is considerably less.

This absorption of the carbonic acid gas, the cultivator should clearly understand, influences in a great degree the composition of the plant. All those vegetable, carbonaceous, nutritious substances which are found in plants, such as gum and sugar, are increased in quantity by its copious supply; for when this gas is no longer secreted by the plant, its health becomes languid, and its composition more watery. Thus a Bysus vegetating in the dark (when carbonic acid gas is emitted by plants), was analyzed by M. Chapital, and found to contain only 1-89th of its weight of carbonaceous matter; but when, after it had been allowed to vegetate for 30 days in the light, it was again examined, it was found to contain 1-24th of its weight of carbonaceous matter. Similar results were obtained by M. Sennebier, who found that when plants were
made to vegetate in the dark, they contained much less oil than those vegetating in the light,—their resinous matter being then as 2 to 54 compared with those vegetating in the light. They had even less earthy matters by one half; but then they had exactly double the quantity of water that the light-growing plants possessed.

Such, then, are the results of the free access of the carbonic acid gas of the atmosphere to the leaves of plants,—it promotes their growth, increases their vigour, and enriches their secretions. The application of the same gas to their roots, although it has not been examined with the same care as its action upon their leaves, is yet evidently attended with the highest advantage. Thus, this gas is one of the constant products of putrefaction, wherever this is going on; as over stagnant drains, dung-heaps, and other putrefying matters: there vegetation is sure to be rankly luxuriant, and that, too, in situations where the roots of the plants are far removed from immediate contact with the decomposing organic matters. This may be easily shown by the repetition of a very simple experiment, which was first made by Davy. This great chemist filled a glass retort, capable of containing three pints, with the hot, fermenting dung and litter of cattle, and examined the elastic fluids which were generated. In 35 cubic inches which were thus produced in 3 days, he found 21 of carbonic acid gas, the remainder being chiefly nitrogen; and after thus ascertaining the composition of these gases, he introduced the beak of another retort, filled in a similar manner, in the soil under the roots of some grass growing in the border of a garden. In less than a week, a very remarkable effect was produced on the grass exposed to the action of these gaseous matters of putrefaction; their colour became deeper, and their growth was much more luxuriant than the grass in any other part of the garden. And hence, too, is derived one of the chief advantages of applying organic matters to the soil, and that in as immediate contact with the crop as possible, just as is effected when manures are added to the soil by the drill; for the roots or leaves of the plants are, by the adoption of this plan, immediately in contact with the evolved carbonic acid, and other gases of putrefaction; they are thus readily absorbed as they are generated, and nothing is lost by escaping into the atmosphere.

The gas, in fact, is instantly yet gradually transmuted from the putrefying products of the farm-yard into the flour of the wheat or the nutritive matters of the grasses. And there is yet another chemical reason why the manure-drill or any other machine should be adopted by the farmer to bring, as closely as possible, every plant into immediate contact with the decomposing manure he applies to his soil; and that is, the superior readiness with which, in all cases of decomposition, the disengaged substance enters into new combinations at the very instant of its disengagement than it does after it has been completely formed. Thus, to give an instance, during the putrefactive fermentation of vegetable substance, a quantity of nitrogen is disengaged; and if this takes place under certain favourable circumstances—such as the presence of calcareous matters, potash, and a dry, warm temperature at the moment it is formed—the nitrogen combines with oxygen, forms nitric acid, which unites with the potash, and thus nitrate of potash, or saltpetre, is formed; but if the nitrogen once fairly disengaged, almost every endeavour of the chemist has failed in making it unite with oxygen so as to form the acid of saltpetre.

In every way, therefore, in which the question of applying manures in immediate contact with the roots of plants can be viewed, the more advisable does the adoption of the practice appear.

The important services of the carbonic acid gas of the atmosphere to vegetation have been illustrated in various ways by more than one able chemist. That given by Professor J. F. Johnston, in his able Lectures on Agricultural Chemistry, p. 218, is perhaps the most recent and the most practical. He observes, “If we were to examine the soil of a field on which we are about to raise a crop of corn, and should find it to contain a certain per centage, say 10 per cent. of vegetable matter (or 5 per cent. of carbon), and after the crop is raised and reaped should, on a second examination, find it to contain exactly the same weight of carbon as before, we could not resist the conviction that, with the exception of what was originally in the seed, the plant, during its growth, had drawn from the air all the carbon it contained. The soil having lost none, the air must have yielded the whole supply. Such was the principle on which Boussingault’s experiments were conducted. He determined the per centage of carbon in the soil before the experiment was begun; the weight added in the form of manure; the quantity contained in the series of crops raised during an entire rotation or course of cropping, until, in the mode of culture adopted, it was usual to add manure again; and, lastly, the proportion of carbon remaining in the soil. By this method he obtained the following results, in pounds per English acre:—From a course of 1. Potatoes or red beet, with manure; 2. Wheat; 3. Clover; 4. Wheat; 5. Oats. Carbon in the manure, &c., 2513 lbs.; carbon in the crops, 7544 lbs.; difference, or carbon derived from the air, 5031 lbs.”

The result of this course indicates that the land, remaining in equal condition at the end of the four years as it was at the beginning, the crops collected during these years contained three times the quantity of carbon present in the manure, and therefore the plants, during their growth, must, on the whole, have derived two-thirds of their carbon from the air.

Oxygen.—Oxygen gas, or vital air, which constitutes 21 per cent. of the bulk of the air we breathe, is absolutely essential to the growth of plants. If this is withdrawn from the atmosphere, they will no longer vegetate,—their leaves will not grow, nor discharge their functions. But this use of oxygen by the leaves of vegetables is confined to the night; it is only in the dark that they absorb it. During this absorption they are in a condition of rest; it is only in the light that they are able to use it.
GASES.

Saussure continued his researches upon the uses of oxygen gas to vegetation. He found that it was essential to many of its functions, that it was absorbed not only by the leaves, but by the roots of plants,—that it then combined with carbon, and the carbonic acid gas thus formed was thence transmitted to the leaves to be decomposed: the very stems and branches of plants absorb it, and its presence is essential to the expansion of flowers; in its absence, seeds will not germinate, and hence the reason why they will not vegetate when placed beyond a certain depth in the soil. The quantity of oxygen gas combined during their vegetation, by equal weights of different seeds, varies considerably. Wheat and barley consume less oxygen than pease, and pease less than common broad and kidney-beans—the latter consuming \( \frac{1}{9} \) th part of their weight, while wheat and barley, during their germination, only absorb from \( \frac{1}{10} \) th to \( \frac{1}{9} \) th of their weight of oxygen gas. Recent experiments have shown also, that the more water is impregnated with oxygen gas, the more excellent are its effects when employed for the purpose of watering plants; and hence one of the causes of the superiority of rain-water, every 100 cubic inches of which contain 3'5 of oxygen gas. Some recent experiments were made by Mr. Hill, which clearly demonstrated these facts. Hya-
cinths, melons, Indian corn, and other plants, were watered for some time with water impregnated with oxygen gas; the first grew with additional beauty and luxuriance, the melons were improved in flavour, the Indian corn increased in bulk, so as "to equal in size most of those imported from North America," and all of them grew more vigorously.

The uses, therefore, of oxygen gas to plants are many and important, and accord with the conclusions which naturally suggest themselves from the results of the analysis of vegetable substances, from whence oxygen is never absent; it must be, therefore, one of the necessary supporters of vegetable life.

**Nitrogen.**—This is the last atmospheric gas which exerts its influence upon vegetation, and enters in small proportions into the composition of plants. Entering in the large proportion of 79 per cent., into the composition of the atmosphere, it is yet supposed to exert but a slight influence upon vegetation. It is found in much smaller proportions in plants than either oxygen gas or carbonic acid gas, although recent researches have shown that it is much more commonly present in vegetable substances than was once supposed; and as I have elsewhere observed (Johnson on Fertilizers, p. 338), that it exerts a more sensible influence upon their growth than is commonly believed, is very certain, and that the proportion of it present in them varies with the different states of their growth, has been clearly shown by the experiments of Mr. Robert Rigg, who found in 100 parts of

It is also well worthy of the farmer's attention, that Mr. Rigg found that whereas barley was made to vegetate in the shade, the increase in the quantity of its nitrogen was nearly 50 per cent., but when vegetating exposed to the direct rays of the sun, the increase was only 30 per cent; and he also made the observation, that the more rapidly the plants vegetate, the more nitrogen they are found to contain. It is also well known to the cultivator, that plants growing in the shade are generally of a deep red colour, vegetating with much luxuriance, and that certain animal manures applied to plants produce similar results in a remarkable degree, such as gelatin, oils, urine, blood, fish, ammonia, &c. Now these fertilizers all contain nitrogen, and which gas must be evolved in some shape or other during their decomposition in the soil;--gelatin, containing 16-698 per cent., albumen, 15-705, the fibrin of blood 19-934, urea 46-66 per cent; and although nitrogen usually exists in plants in very small portions, yet I am entirely disposed to agree with Mr. Rigg in his conclusion, that more attention should be paid than has hitherto been done, in the examination of vegetable substances, "to those products, which, though so minute in quantity as to be with difficulty detected in our balances, have nevertheless been wisely assigned to discharge the most important functions." (Phil. Trans. 1838, p. 406.)

Such, then, are the essential and highly important uses of the three gases of the atmosphere, nitrogen, oxygen, and carbonic acid, to all vegetation; an attentive consideration of which will explain to the farmer the cause of many of the phenomena he daily witnesses, and suggest to him an unanswerable argument for the adoption of those modes of cultivating his land, the results of careful and scientific investigations, which such chemical researches suggest and render intelligible.

Thus, the absolute necessity for all crops receiving a regular supply of carbonic acid gas, will explain to him why his crops always yield an inferior produce when they are surrounded by thick plantations of timber trees; and why the portion of all kinds of plantations growing on the side of the field the most exposed to the winds is almost always of the most luxuriant growth; it will explain to him the reason why many skilful farmers drill their corn so that the most prevalent winds may, with the more facility, circulate among the rows, instead of across them; and why all farmers find that their crops prosper better in moderately windy weather than in calms; since in all these instances, and in many other well known popular observations of the same kind, the copious supply of the carbonic acid and oxygen gases of the atmosphere is naturally impeded by thick plantations of other vegetable substances, and promoted by the winds.

The consumption of oxygen gas by the roots of plants, and their increase of growth and vigour when their usually impeded supply is increased, is equally fraught with instruction to the cultivator; for it serves to explain the reason why stirring the soil around the roots of trees, according to the fashion of the early olive and olive cultivators of Italy, or merely disturbing the rows of cabbages and turnips, as practised by the best English farmers, is attended with decided advantage, since it suffers the air to have more free access to their roots. It renders apparent, too, one of the chief reasons why mere subsoil-ploughing adds so materially to the luxuriant produce of even the poorest cultivated lands, since, as the soil is deepened and pulverized, the atmosphere more freely and more copiously penetrates to the roots of the vegetation it supports. The same fact explains the advantages of deep ploughing, of sub-turf ploughing, and of trenching; why the indolent farmer in vain tries to render productive his shallow-ploughed lands; and why, when the industrious cottager encloses his garden from the barren waste, too poor to sufficiently manure it, he yet renders it productive of excellent crops, by merely trenching it to the depth of 18 or 20 inches.

And it is vain for the cultivator to urge that this benefit is not to be mainly attributed to the freer circulation in the soil of the gases and watery vapour of the atmosphere, but that it is owing to the mixture of the surface-soil with the substratum. For such a conclusion is not only opposed by the fact, that many soils do not differ in composition from the substratum on which they rest, and yet are materially benefited by trenching or subsoiling, but is contradicted by many agricultural facts with which every cultivator is familiar; and if any other answer were requisite, that would be amply supplied by the recent experiments of Sir Edward Stracey, with his new sub-turf plough, which cure these gases under the turf at a depth of ten inches, and disturbs and loosens very effectually the soil; but when the plough has passed under, every thing resumes its former position, although every portion has been thoroughly agitated, and rendered more permeable to the atmosphere. The soil is neither displaced nor mixed, and yet this mere loosening is productive of the highest advantage, the produce of grass is extensively and permanently improved. Sir Edward Stracey, after describing the increased produce of the grass as being very remarkable, tells us that there are no marks left by which it can be known that the land has been so ploughed, except from the lines of the coulter, at the distance of about fourteen inches from one another. In about three months from the time of ploughing, these lines are totally obliterated, and yet the quantity of aftermath, and the thickness of the bottom, have been the subject of admiration of all his neighbours. (Journ. Eng. Agric. Soc. vol. i. p. 253.)
GASES.

And then, with regard to the carbonic acid and the carburetted and sulphuretted hydrogen gases evolved during the putrefaction of animal and vegetable manures, the discoveries of the chemist are equally instructive and confirmatory of the observations of the intelligent farmer. The one finds that these gases, so grateful to the farmer’s crops, are the most copiously emitted in the early stages of putrefaction; that these gradually decrease in volume as the fermentation proceeds; and finally, when the mass is reduced to the state of vegetable mould, cease altogether. Now, the farmer is well aware that the manure of the farm-yard, in common with all organic decomposing fertilizers, is by far the most advantageously applied, and produces the most permanent good effect when it is used in the freshest state that is at all compatible with the destruction of the seeds of weeds, with which such collections usually abound. He is aware, that in all situations where the gases of putrefaction are emitted, such as near to stables, marsh-ditches, covered drains, &c., that there vegetation of all kinds indicates by its rapid growth, that some unusual supply of nutriment is afforded; the gardener in his best arranged hot-beds notices that the gases which ascend from his piles of litter through the earth (which earth is not in immediate contact with the dung) produce the same effects long after all the warmth of putrefaction has subsided. The growth of some of his plants is in this way stimulated, he says, in an extraordinary manner. These facts and observations are entirely confirmed by those of the chemist. He notices that all the gases of putrefaction are precisely those which are the most nourishing to the growth of plants; that air which has been spoiled by the presence of the gases evolved in putrefaction, or by the breathing of animals, is exactly that which is the most grateful to vegetation; and that where these gases are applied to the roots of plants in the most skilful manner, so as to insure a regular, steady supply, that then the plant is enabled to vegetate in a most vigorous and unusual manner. Thus, when green manures, such as sea-weed, buckwheat, leaves of trees, fern, &c., the most slowly decomposing of all vegetable manures, are applied to the roots of plants, the effects, according to chemical experiments, are excellent; and, as I have elsewhere observed, the farmer assures us that they are so. He tells us that all green manures cannot be employed in too fresh a state; that the best corn is grown where the richest turf has preceded it; and that where the roots, stalks, and other remains of a good crop of red clover have been ploughed in, that there an excellent crop of wheat may be expected; and that when buckwheat is ploughed into the soil, this is most advantageously done when the crop is coming into flower. The chemist again explains this without any difficulty. Davy and other chemists have shown that when the flower is beginning to appear, then the plant contains the largest quantity of easily soluble and decomposable matters; and that when these green plants are in this state buried in the soil, their fermentation is checked and gradual, so that their soluble or elastic matters are readily absorbed by the succeeding crop, and every portion of it becomes subservient to the demands of other plants. No cultivator, perhaps, ever examined this question more accurately, or tried his experiments with more neatness, than the late excellent President of the London Horticultural Society, the lamented Knight of Downton; and these were the more valuable, from being insututed to ascertain the state of decomposition in which decaying vegetable substances could be employed most advantageously to afford food to living plants. This he clearly proved, however erroneous were his explanations of his own observations and discoveries. One of his experiments with a seedling plum tree was very remarkable. He placed it in a garden-pot, having previously filled the bottom of it with a mixture of the living leaves and roots of various grasses, covered over with a stratum of mould. The plant appeared above the surface of the ground in April, and, during its growth in the summer, was three times removed to larger pots in the greenhouse, in every case the bottom of them being filled with a mixture of living leaves and roots covered over with a layer of mould; and by the end of October its roots occupied a space of about one-third of a square foot, it having then attained the extraordinary height of nine feet seven inches. This experiment was varied by Mr. Knight in several ways: he drilled turnip-seed over rows manured with green fern leaves, and compared the produce with other rows of turnips by their side, manured with rich vegetable mould; and in all cases those which grew over the gradually fermenting green fern not only grew more rapidly than those treated in any other manner, but they were distinguished from all others in the same field by their deep green colour. Now, when the gases of putrefaction are mixed with the roots of all growing crops, this is exactly the effect produced. The most foul, stinking water, even when transparent, is ever the most grateful to plants; that from stagnant ditches, which has always a peculiar taste from the carburetted hydrogen it contains, is excellent. Every gardener prefers that from ponds, however clear; the purer water from wells, he tells you, is very inferior, it is too cold; but then he confesses that even warming it does not render it equal to that from stagnant places in its effects upon his plants; so that, in whichever way the experiment is made, there is no doubt of the value of these gases to the cultivator’s crops, and he will readily therefore agree with Knight in the conclusion, that any given quantity of vegetable matter can generally be employed in its recent and organized state with much more advantage than where it has been decomposed, “and no inconsiderable portion of its component parts have been dissipated and lost during the progress of the putrefactive fermentation.” (Trans. Hort. Soc. vol. I. p. 248.)

Aqueous Atmospheric Vapours.—The last substance ever present in the atmosphere in considerable proportions, and which bears a very important relation to the prosperity of the farmer’s crop, is the aqueous vapour, without whose unvaried presence no commonly cultivated plant could flourish, and few exist at all.
GASES.

Providence, therefore, has ordained that this should be ever ready to meet the demands of vegetable life, and that its quantity should vary with the temperature, increase with the warmth when its pressure is most needed by the plant, and diminish in proportion as the air becomes cooler. Thus, at a temperature of 50°, supposing it to have a free communication with water, the atmosphere contains about 1-75th of its weight of vapour; but when its temperature is increased to 100°, then its proportion of water is increased to 1-21st of its weight; and this beautiful arrangement is the more important, as Davy well observed, in the economy of nature, because, in very intense heats, and when the soil is dry, the life of plants is mainly, if not entirely, preserved by this absorbent power of their leaves and the earth in which they grow; and, happily, this watery vapour is most abundant in the atmosphere when it is most needed for the purposes of life; when other sources of its supply are cut off, this is most copious. The amount, however, of the atmospheric vapour varies with the kind of wind. Those which have passed over warm seas contain more than those which have traversed extensive dry countries; that which crosses the hot, dry sands of Asia and northern Africa is so dry that it scorches, as it were, all the adjoining countries. It is the cause of the sirocco of Malta being so noxious, and why the English farmer finds that an easterly wind, in England the driest of all winds, is the least propitious to vegetation. He well knows, on the other hand, that the westerly or south-western breezes, the most watery of all winds in Britain, which come to his fields surcharged with all the vapours of the Atlantic, are precisely those which bring with them luxuriance to his crops, and clothe his woods with verdure.

The cultivator will derive many advantages from a careful investigation of the support yielded by the vapour of the atmosphere to his plants. He will perceive that its unrivalled presence affords an additional reason why the air should be allowed to circulate freely through the well-plimered and loosened soil, to the roots of all growing crops; and let him, above all, avoid the common erroneous conclusion, that the atmosphere is ever dry, that it no longer contains watery vapour; for the real fact is, he will find the very opposite to the common vulgar conclusion. The chemist's laborious investigations have clearly demonstrated, that though the watery vapour varies in amount, yet it is never absent from the atmosphere, but that it happily always the more abounds where the cultivator's crops need its assistance most; it is then the most able to furnish the roots of his grain crops with all the moisture they require; and if it is unable to penetrate to them, the fault is not in the wise economy of nature, but in the carelessness of the cultivator, who is either too inattentive to see the advantages which he might thus freely derive, or too indolent to loosen the case-hardened soil, which prevents the entrance of the requisite supply of moisture. One of the causes of the unproductive ness of cold, clayey, adhesive soils, as Davy well remarked, is, that the seed is coated with matter impermeable to air. The farmer can convince himself of these facts by the simplest of all experiments. Let him merely use his rake or his hoe on a portion of a bed of wheat, of turnips, or lettuces, or any other kind of crop, and let him, in the driest weather, merely keep this portion of soil loose by this gentle stirring, and he will find that, instead of prejudicing his crop by letting out the moisture, as is often ignorantly supposed, something is evidently let into the soil; for the portion thus tilled will be soon visibly increased in luxuriance by the mere manual labour thus bestowed; and in this experiment, which I have often tried, I am supposing that both the portions of the ground are equally free from weeds; that in every other respect the treatment of both the tilled and undisturbed portions of the experimental plot is exactly the same. To a very great extent, some of the best of the English farmers have long found out these facts, and have acted upon the discovery. The horse-hoe of the east and south of England, in the driest day of the summer, may be seen at work in the sandly turnip-fields of Norfolk and Suffolk, with unvaried regularity, not for the mere destruction of weeds, for these are not the abounding tenants of such skilful farmers' lands, but for the chief and highly benefical purpose of increasing the circulation of the gases and vapour of the air. "The longer I keep stirring the soil between my turnip drills," said Lord Leicester to me, some years since, "in dry weather, the better the turnips grow."

The same uniform presence of aqueous vapour which marks the atmosphere in all times and seasons, in a still more remarkable degree distinguishes its constituent gases, for these never vary in amount in any times, or seasons, or countries. The atmospheric air has been analyzed, when obtained from the lowest valleys, and the tops of the highest mountains, in crowded cities, and in the open country, but its composition was always found to be the same, viz., nearly 21 per cent. of oxygen, and 79 of nitrogen, and from 1 part in 500 to 1 part in 800 of other fixed gases.

Such, then, are the principal matters contained in the atmosphere, or added to it by pre-treatment, which influence the progress of vegetation. That there are other matters occasionally present in the air, which are in all probability grateful to vegetation, is very certain; our very senses tell us that there are clouds of smoke, which is a mixture of carburized and sulphuretted hydrogen, soot, and vapour, hourly hovering over all large towns and cities, and which huge mass of winds disperse over the country. Of these the soot, and finely divided earthy matters with which it is combined, are very speedily deposited; it is one reason why the lands near to populous places are very commonly rich and fertile. Ammonia has been detected in rain-water. That other substances also exist in the air in minute, yet active proportions, is very certain, though they are too subtle to allow the chemist to detect them; thus, to such finely divided matters the physician attributes the progress of contagion—the chemical philosopher the aroma of flowers, and of many other sub-
GAS-WORKS.

stances. Certain diseases follow the course of particular winds; and the stones or fireballs, and similar substances, which have in all ages been seen to fall from the atmosphere, completely baffle the scientific conjectures of the meteorologist. With such speculations, however, the cultivator need not disturb himself: resting contented with the knowledge he possesses of the invaluable and essential powers of the known gases and vapours of the atmosphere to assimilate and sustain the growth of his crops, and adopting in consequence those improved modes of cultivation which that knowledge suggests, he will patiently await the time when the future discoveries of science shall still further enlarge his sphere of usefulness, by enabling him to draw forth those latent powers of production which, there is every reason to believe, yet remain hidden in the soil. (Quart. Journ. of Agr. vol. ii. p. 32.)

Some curious experiments upon the gases hurtful to vegetation were made by M. Macon. Some plants of euphorbium, mercury, groundsel, cabbage, and sowthistle, with their roots, were placed in the morning in a large vase into which chloride of lime had been introduced. The roots were then separately soaked, and the quantity of chlorine disengaged was by no means sufficient to destroy the vegetable tissue. At night the plants had not suffered, and the smell of the chlorine was unchanged. The same plants placed in the same vase without any addition of chlorine, were found quite faded the next morning, with the exception of the cabbage. The odour of the chlorine had entirely ceased, and had been succeeded by a disagreeable acid smell. The experiment being several times repeated, by rendering the extraction of chlorine more considerable, produced the same result, and the plants supported an atmosphere strongly impregnated with chlorine by day, while a much weaker dose always destroyed them during the night. Similar results were obtained when the vapour of nitric acid was admitted into a mixture of nitrogen gas, a phosphuret of hydrogen, and a nitric acid gas, and the plants found to be still alive. In another experiment, M. Macaire was of opinion, from these trials, "that many of the gases are hurtful to vegetation; but that they act on them only during the absence of light." (Quart. Journ. of Agr. vol. v. p. 301.)

GAS-WORKS, the Refuse Matters of, as Fertilizers. It is only within these few years that the attention of the farmer has been attracted to the various matters produced by the gasworks now so common in all parts of England. This attention, however, is confined at present to only particular localities: while in one district it is zealously used, and bought up with avidity, in others it appears to be totally neglected. In the vale of Kennet the farmers clear away from the gas-works all the refuse matters they can obtain, even at advanced prices. Those of the valley of the Itchin, in Hampshire, find it, in small proportions, an excellent dressing for grass.

The refuse matters which are produced during the distillation of pit-coal in the gasworks, consist of three substances; the ammoniacal liquor, the hydro-sulphuret of lime, formed by passing the gas through lime to deprive it of its sulphuret hydrogen, and the coal-tar; these substances are worthy of the cultivated attention, for they are all fertilizers of considerable value. Let us examine them in the order in which I have enumerated them.

1. The ammoniacal liquor obtained from gasworks is an impure solution of the carbonate and acuate of ammonia; and these salts, there is little doubt, not only act as stimulants to plants, but both the acids and the ammonia, when decomposed, furnish direct food to, or constitute parts of, vegetables. Carbonate of ammonia has been detected in the stinking goose-foot (Chenopodium olidum), by MM. Chevalier and Lassaigne, and it probably exists in other plants which are distinguished for their powerful disagreeable odour. If the plants do not contain ammonia, or its salts, it is the ammonia either in the soil or the air which affords them the nitrogen which enters into their composition. (Annals of Phil. vol. xii. p. 231.) Hydrochlorate of ammonia has been found in wood by M. Chevreul. (Ann. de Chim. 68, p. 284.)

There are many testimonials in favour of the use, as fertilizers, of the salts of ammonia, either in their pure state, or as found in an impure combination with soot, or in the liquor of gas-works. "Soot," said Davy, "owes part of its efficacy to the ammoniacal salt it contains. The liquor produced by the distillation of coal contains carbonate and acuate of ammonia, and is said to be a very good manure. In 1808, I observed that the growth of wheat in a field at Rochampton was greatly assisted by a very weak solution of acuate of ammonia." (Lectures, p. 342.) The experiments of Mr. Robertson with soot clearly show the fertilizing effects of the soluble portion of it, which is principally the salts of ammonia. He mixed together, in order to form a liquid manure, six quarts of soot in a hoghead of water. "Asparagus, peas, and a variety of other vegetables," says this intelligent horticulturist, "I have manured with this mixture with as much effect as if I had used solid dung; but to plants in pots, particularly pines, I have found it admirably adapted; when watered with it they assume a dark, healthy green, and grow strong and luxuriant." (Gard. Mag. vol. ii. p. 18.) Care must be taken in using this, and all other liquid fertilizers, not to make the solution too strong; it is an error into which all cultivators are apt to fall in their early experiments. Davy was not an exception; from making his liquids too concentrated, he obtained results which widely differed from his later experiments. (Lectures, p. 170.) There is no doubt but that the salts of ammonia, and all the compound manures which contain them, have a considerable forcing or stimulating effect upon vegetation. In the experiments of Dr. Belcher, upon the common garden cress, by watering them with a solution of phosphate of ammonia, the plants were 15 days forwarder than other plants growing under similar circumstances, but watered with plain water; and he also describes the experiment of a Mr. Gregory, who, by watering one-half of a grass field with liquor (which abounds with the salt of ammonia),
nearly doubled his crop of hay. (Com. to Board of Agr. vol. iv. p. 416.)

"It is probable," says Mr. Handley, "that the ammoniacal liquor which abounds in gas-works, and which, when formerly allowed to run waste into the Thames, was said to destroy the fish and prejudice the quality of the river water for human consumption, and which is still thrown away throughout the country, except at a few works where they manufacture sal ammoniac, will, ere long, be extensively used as a manure, either through the intervention of the water-carts, or for the process of saturating and decomposing soil or vegetable matter. A very satisfactory illustration, on a small scale, has recently been submitted by Mr. Pain. He put into a vessel some leaves of trees, saw-dust, chopped straw, and bran, to which he applied ammonia, and closed it up. In about three weeks the whole was reduced to a slimy mass: he then stirred it, and added a little more ammonia; and when submitted to the English Agricultural Society, it was reduced to a black mass of vegetable mould, strongly impregnated with volatile salts, and in comminuted particles similar to surface peat mould. When applied in its liquid form to grass, like salt, it apparently destroys the plant; but the spot is distinguished by increased verdure the succeeding year." (Eng. Agr. Soc. Journ. vol. i. p. 46.)

Mr. Paynter, of Boskenna, in Cornwall, has given the result of an experiment made with the water in which street gas had been cleansed, on a piece of barley land. A quarter of an acre was taken in the middle of a field of rather close soil, in a granite district. The land was of average quality; the gas-water was distributed over the quarter acre by a contrivance resembling that of a common watering can, and at the rate of 400 gallons to the acre; about a week before seed time, the rest of the field was manured in the usual way. The difference both in colour and vigour of the barley plant was so strikingly in favour of the part manured by the gas-water, that persons passing within view of the field almost invariably came to inquire about the cause. The yield also was superior, as well as the after-notice, the field having been laid down with the barley." (Ibid. p. 45.)

The refuse Line of Gas-Works.—This powder is produced by passing the gas through dry lime, in which operation the earth combines with a quantity of sulphureted hydrogen, from which the coal gas needs purifying, and is partly converted into hydro-sulphuret of lime; in the state that the powder is usually vended by the gas manufacturers, it contains a considerable portion of uncombined lime. The hydro-sulphuret of lime has a bitter and acid taste; it is soluble in water, and has the peculiar disagreeable smell of sulphuretted hydrogen. When mixed with or spread upon the soil, it gradually decomposes, a portion of hydrogen separates from it, and it is converted into sulphuret of lime, which, by absorbing oxygen from the atmosphere, finally becomes sulphate of lime. There is no reason, therefore, to doubt the fertilizing properties of this manure; but it is too powerful in its effects upon vegetation, to be used in the large proportions in which it has been sometimes employed; and it should not, for these reasons, be added to the soil immediately in contact with the seed. It is generally to be obtained at a very moderate rate, and by its gradual conversion to sulphate of lime (gypsum), it must be a very excellent addition to those soils which are described by the farmer as having become "tired of clover."

"In many parts of the country," says Mr. Handley, "where gas-works are established, the refuse gas become an object of interest to the agriculturist, as containing many of the essentials of the most effective manures. The refuse lime which was formerly an inconvenience to the manufacturers, and was carted away as valueless rubbish, is now contracted for by the neighbouring farmers (in an instance within my own knowledge at 7s. 6d. per chaldron), and applied either in compost, or in a direct form, to the land, where, in addition to the usual operation of lime, it is said to furnish a protection against many of the noxious grubs and insects." (Ibid.)

Gas Tar.—This substance being produced in smaller quantities, and employed very commonly as a paint, has not been used as a manure to any extent; but wherever it can be obtained (as I am aware it ever can in some places, almost for the expense of carriage), it is an article every way worthy of the farmer's notice. It is composed entirely of substances which enter into the composition of all plants, is gradually decomposed in the soil, is powerful in its effects, and still more so from its containing a considerable portion of the carbonate and acetate of ammonia; hence it is best applied mixed with earth, so as to be easily and evenly spread over the ground. These facts will explain some of the phenomena witnessed in the recent experiments of Mr. Bowley with gas refuse, at Sidlington, Gloucestershire. He says (Farm. Mag. vol. ix. p. 197), "I have long used the refuse of the gas-house as a manure; my usual practice is to form out my compost-heap with long dung about three feet deep, pour the coal tar regularly on top of it, then put another layer of dung on top of that, throw up the lime on the top, allow it to remain in this state two or three months before it is turned. The lime should not be under the tar in the first instance, as the tar will find its way through the dung, and unite with the lime into a hard cement, in which state, even if, with considerable labour, it is broken into small particles, I believe it to be of little service on the land."

"After pursuing the above system for some time, I resolved to try some experiments with each in its unsophisticated state. I accordingly commenced with the tar, which I had poured out of a watering-pot, in a small stream, regularly over about half an acre in a field of rye-grass; this was done in February, 1838. Soon afterwards, the seeds presented the rather singular appearance of having been burnt in stripes with a hot iron, for the tar had completely destroyed all it touched, and I was told I had poisoned the land, and it would never recover itself; however, in June, I noticed that the
GELATIN.

Grass between the streams of tar looked more luxuriant, and the sheep fed on it in preference to the other parts of the field. In the autumn the whole was ploughed, and sown with wheat, which looked much more flourishing on the half-acre dressed with tar than anywhere else; the difference was so conspicuous from the first, that the most casual observer could not pass without remarking it; and at the present time (August, 1809), there is a heavy crop on it ready for the sickle, while the rest of the field is light, and will not be ripe for a week or ten days. I put some tar in the same way on a piece of land, a month before it was ploughed for spring vetch; the vetches were sown two weeks after the plough, and many of them were destroyed; but the crop of wheat which succeeded was benefited equally with the one in the other experiment. I have tried the lime with great advantage, putting from 12 to 15 cart-loads to the acre, but I find it is better to remain a time before it is ploughed in. All the places were tried on a cold, sandy clay, worth about 10s. per acre. In these experiments, the quantity applied per acre was too large, and the manure in a state much too powerful. It was only where it had become diffused through the soil by time, that its fertilizing powers were apparent.

Coal tar is much improved in effect, when employed as a coating for palings, by mixing it with a small portion, say one-forthieth of its weight, of grease; this is easily united by heating the tar.

GATES. Good gates are no less essential to the respectable appearance of a farm than they are necessary for the convenience of an occupier. There are few outgoings that cost so much and are so little thought of, as the repairing and renewing gates upon enclosed farms. The most common defects are, 1st. Not sufficient height, so that horses and large cattle, when pressing against the gate, break it, however strong it is, as the back thereof comes into contact with that part of the chest of the horse where the collar goes, and without inconvenience he leans his weight against the opposing bar, which, if a few inches higher presses against his neck and windpipe, and he makes no impression upon it. 2d. They are generally hinge-bound, so that in attempting to lift up the head, which is often required to be done, the ledges and braces are either pulled from the back head or broken therein; the person lifting the head having a nine-feet leverage, which enables him to do this mischief. 3d. The places of contact between the brace and the uprights and the ledges are broad, and it being impossible to keep those places of contact dry, the parts become prematurely decayed.

The two great objects to be combined in a gate are strength and lightness. In the Cultivator and some other American agricultural periodicals, many useful observations, with drawings of gates, may be found.

Much has been written on the subject in England; see Quart. Journ. Agr. vol. i. p. 727; and the Trans. of the High. Soc. vol. ii. p. 260, where a self-acting gate, suited for the transfers to parks or the approaches to mansion houses, is figured and described. There is also a useful essay "On the Construction of Gates for the common purposes of a Farm, the causes of their Decay, and the manner of improving them," in the Commn. to Board of Agr. vol. vii. p. 144; see also Loudon's Encyc. of Agriculture.

Among the excellent observations upon the subject of farm gates, to be met with in the agricultural periodicals of the United States, we would particularly refer to a paper in the Cultivator, (vol. ii. p. 132.) headed Parker's Farm Gate, giving the most minute directions for constructing, accompanied with drawings of the gate and its several parts. See also Cultivator, vol. vii. p. 124, for the plan and drawing of a cheap gate, which never sags; and more especially the same valuable periodical, vol. viii. p. 53, for Mr. Bennett's Communication on Ornamental Gates, accompanied with descriptions and drawings.

GATHERING. Provincially, rolling corn-swaiths into cocks or bundles. Also a popular name for Abscess, which see.

GAVELKIND. An ancient custom or tenure annexed to all land in the county of Kent (not especially exempted), and some other parts of England, and which extensively prevails in Ireland, by which the land of the father is equally divided at his death among all his sons, or the land of the brother among all his brethren if he have no issue of his own. Tenure in gavelkind is considered by Blackstone to have been in the nature of free socage. In most places the gavelkind tenant had the power of devising by will before the statute of wills. The same custom seems to have been prevalent in Wales, where all gavelkind lands were made descendable to the heir at common law by the stat. 34 & 35 H. 8, c. 36. In Kent the lands have for the most part been disgavelled, or deprived of their customary descendable quality by particular statutes; but lands in Kent are presumed to be gavelkind unless the contrary be shown. Mr. Ross, in his Survey of Loudonerry, gives an interesting account of this custom and its pernicious effects. This notion of the equal and unalienable right of all the children to the inheritance of their father's property, whether land or goods, which is so general in Ireland, is one great obstacle to improvement. However just and reasonable the opinion may be in theory, it is ruinous in practice. In spite of every argument (says Mr. Ross) the smaller Irish landholders continue to divide their farms among their children, and these divide on until division is no longer practicable; and, in the course of two or three generations the most thriving family must necessarily go to ruin.

GEERS. A country phrase for the harness of draught or team horses.

GELATIN. In chemistry the name given to an abundant proximate principle in animals. It is confined to the solid parts of the body, such as tendons, ligaments, cartilages, and bones, and exists nearly pure in the skin; but it is not contained in any healthy animal fluid. Its leading character is the formation of a tremulous jelly, when its solution in boiling
GELDING.

water cools; and it may be repeatedly liquefied and again gelatinized by the alternate application of heat and cold. Isinglass, glue, and size are various forms of gelatin, the first being this substance in a very pure state, obtained by washing and drying the swimming bladder of the sturgeon (Leipencer huso) and some other fish. Its most distinctive chemical character is the formation of a dense white precipitate when its solution in warm water is poured into an infusion of galls, or that of any other astrigent vegetable; the substance formed in such cases is a tannate of gelatin, by the union of the tannic acid with the gelatin. Gelatin is a semi-transparent and colourless when pure. Its consistency and hardiness vary considerably. The best kinds are very hard, brittle, and break with a glassy fracture. Its taste is insipid, and it has no odour. A solution of one part of gelatin in 5000 of water is rendered slightly turbid by the addition of a strong infusion of galls. Gelatin, as an article of food, is not so nutritious as is generally supposed.

The ultimate components of gelatin are:

100 lbs. of bones yield about 25 or 27 lbs. of gelatin. It is used for making carpenter’s glue, as the fat in the bones gives it a bad taste, and renders it unfit for soup. See Glue. (Braid’s Dict. of Science.)

GELDING. In farriery, a castrated animal; and also the act of castrating. In performing this operation, attention should be paid to the age, and also the season of the year. The most proper seasons are either the early spring months, or those of the autumn.

GENTIAN (Gentium). This, in England, is an extremely beautiful genus of plants; the roots of which form one of the principal bitters of European growth. The stems and roots of most of the species, especially the autumnal gentian (G. amarella), the field gentian (G. campestris), and some of the foreign species are tonic, stomachic, and febrifuge. That which is principally used in medicine is the root of the great yellow gentian (G. lutea), which is imported from Germany. The generic name was given to them after Gentius, King of Illyria, who is reported to have first experienced the virtues of the plant. The species of gentian, indigenous to England, according to Sir J. E. Smith, are six in number.

1. The Marsh Gentian or Calathian violet (G. pneumonanthe). A perennial herb, found on moist, turfy heaths, blooming in August and September.

2. The Dwarf Gentian (G. acaulis). A perennial, but very doubtful native, found on mountains. The stems generally very short, rising from the centre of tufts of leaves, single-flowered. The flower, which blows in June or July, is large, often two inches long, exquisitely beautiful, of a rich blue in the limb, paler in the tube, which is dotted internally with black. Root fleshy and branching.

3. The Spring Gentian (G. verna). A perennial, growing in barren, mountainous situations, but rare, flowering in April.

5. The Autumnal Gentian (G. amarella). An annual plant, growing frequent in limestone and chalky pastures, flowering in August and September.

6. The Field Gentian (G. campestris). An annual, flowering in September or October, growing on elevated pastures, or upon green hills towards the sea-coast, where the soil is often chalky; the roots are very bitter and tonic. It is sometimes known as yellow caucaua and blue gentian.

Most of the herbaceous kinds of gentian grow well in a rich, light soil, but some require to be grown in peat; indeed, all will grow much stronger in it. Several of the species should be grown in pots, placed among alpine plants, and protected in winter. Some of them may be increased by divisions. The annual and biennial kinds may be sown in a dry, sandy situation in the open border; but they must be sown as soon as the seeds are ripe, because, if left till spring before they are sown, they will not, very probably, come up till the second year.

The species of gentian best known in the United States, are:—1. The one called Soapwort (G. saponaria), a handsome plant, frequently found in Pennsylvania and other Middle States, along the margins of swampy rivulets and in low grounds. It flowers in September, and ripens its seed in November. The root, as in all the genus, is bitter and tonic.

2. Yellowish-white Gentian (G. ochroleuca), found in fields and woodlands in the Middle and Southern States, but not so common as the former kind.

3. Hairy, or Fringed Gentian (G. crinita), frequent in hilly, open woodlands and old fields in Pennsylvania, where it is one of the most beautiful autumnal flowering plants in the months of September and October. Its flowers are often destroyed by frost. Though generally described as a biennial, Professor Eaton considers it a perennial. Dr. Darlington thinks it an annual.

Seven or eight additional species of gentian are enumerated in the United States. (Flora Cestriensis.)

GEOLOGY.

GEOLOGY. (ζ, the earth; γαλαγω, a discourse). The use of this science to the cultivator is considerable. The farmer is, in fact, obliged to vary his modes of tillage with the different strata which he tenants, and hence he is often following in practice the very rules, and observing the laws which the science of geology would prescribe, without being aware of the scientific reasons by which his labours are guided. It is a science he will find closely connected with the best modes of cultivating the soil, the drainage of land, the mixture of earths, and other agricultural improvements. From geological observations, the farmer learns the process by which the soils he cultivates were originally formed, their connexion with the substratum, and the readiest mode of improving their constituents; thus, as it is
well observed by Mr. Morton, in his valuable little work on Soils, p. 3. "If we can show an identity of the materials which form the soil with those of the subsoil upon which it rests, we shall obtain a key to a more correct and satisfactory classification of soils than at present exists; their nature and produce, the kind of crops which they are best calculated to produce, and the materials necessary for their permanent improvement will also be more evident."

That such scientific observances of the order of nature cannot but be attended with benefit, is a remark which we cannot too often make to the farmer: it was an observance which Davy long since made, (Lectures, p. 204); he told the farmers of his day, that "the best natural soils are those of which the materials have been derived from different strata which have been minutely divided by air and water, and are intimately blended together; and in improving soils artificially, the farmer cannot do better than imitate the processes of nature;—the materials necessary for the purpose are seldom far distant—coarse sand is often found immediately on chalk, and beds of sand and gravel are common below clay. The labour of improving the texture or constitution of the soil is repaired by a great permanent advantage—less manure is required, and its fertility insured, and capital laid out in this way secures forever the productiveness, and consequently the value, of the land," and again, Dr. Paris, when addressing the Rural and Agricultural Society, remarked, "The composition and arrangement of the different rocks of which a country consists, is always an object of important interest to the liberal and well-informed farmer, for it will generally be found more or less connected with its agricultural economy, and is frequently capable of explaining peculiarities and anomalies which are otherwise quite unintelligible. At the same time a knowledge of them will suggest the best method of improving a soil by exhibiting the nature of its texture and constitution, and the various causes of its sterility." That geological surveys of even particular estates have been attended with considerable benefit, we have the valuable testimony, amongst many others, of Sir J. V. Johnstone, who says (Journ. of Eng. Agric. Soc. vol. i. p. 273), "The geological survey and map of my estate has not only explained the reason of the discrepancy between the soil and productiveness of neighbouring fields—a matter of great interest, and tending to develop the true conditions of vegetable life; but the following positive practical results have been also derived from it. 1st. The knowledge of applying lime to advantage over the property; 2d. Laying down fields to advantage to grass, and where and how to plant wheat; 3d. What trees to plant upon each stratum; and as, he very correctly adds, "Certain soils are so obviously connected with their bases, that we need scarcely ask how geology and agriculture are mixed together;" and to use Dr. Smith's own words, "The strata succeed each other in a certain order, and being delineated, a knowledge of the strata becomes the natural and safe foundation of improvement; and if agricultural chemistry be ever successfully applied to the practical purposes of agriculture, it must be by proceeding with the chemical analysis of soils along the range of each stratum." (Farmer's Almanac.)

And it is quite true, as Mr. Macgillivray remarks (Quarterly Journal of Agriculture, vol. iii. p. 209), that "an experienced agriculturist may judge correctly of the general capabilities of a district from a superficial inspection, and may perceive its adaptation to the cultivation of certain plants, or to the rearing of certain species of animals, in consequence of a single glance of his eye; but how much more precise will be the estimate of him who examines the slopes of the declivities; the depth and quality of the soil; the nature of the subsoil; the distribution of rills, pools, and springs; the kind and disposition of the mineral strata; the existence of limestone beds; the elevation above the level of the sea; the exposure to particular winds; the prevalent atmospheric currents; the frequency of rains and frosts; and all the other physical phenomena which influence a country. Even the nature of the rock itself, independently of other circumstances, discloses the capabilities of the soil, in a degree which could scarcely be imagined by one totally unacquainted with the influence which it possesses."

As my observations on geology in this work will be chiefly confined to its connexion with practical agriculture, I shall not detain the farmer with any of the valuable geological researches which extend far beneath the earth's surface. Indeed, as Professor Brande remarks in his Outline of Geology, p. 32, when speaking of geology, "Its first and leading object is to become practically acquainted with the present state of the earth's external structure, for, excepting of its erust or rind, we know nothing; and all that has been suggested either by theory or experiment, relating to its internal composition, its density, and the constitution of the entire mass, is mere surmise and deductions hastily drawn from superficial observation or unwarranted inferences from imperfect researches." To the student who wishes to make himself practically master of the science, I commend the lectures of Professor Brande, as well as the Outlines of the Geology of England and Wales, by Conybeare and Phillips. To the practical, intelligent farmer, the work On Soils, by Mr. John Morton, will also be very valuable. To this excellent little book I gratefully acknowledge my obligations in this and many other articles.

The best popular description, perhaps, of the position in which the various strata of the earth are placed, is that long since given by Mitchell. "This very ingenious writer," says Brande (Outlines, p. 13), "describes the general appearance of the strata, points out their analogies and differences, adverts to their inclination and disturbance in mountainous districts, and to their horizonality in flat countries; and having explained with much minute and practical perspicuity the arrangement of the strata in England, he exemplifies its universal application to the general structure of the globe, and ingeniously represents it in the following manner.—Let a number of leaves
of paper,' he says, 'of several different colours, be pasted one on another, then binding them up together into a ridge in the middle, conceive them to be reduced again to a level surface by a plane so passing through them as to cut off all the part that had been raised; let the middle now be raised a little, and this would be a good general representation of most, if not all, large tracts of mountainous countries, together with the parts adjacent throughout the whole world. From this formation of the earth, it will follow that we ought to meet with the same kinds of earths, stones, and minerals, appearing on the surface in long narrow slips, and lying parallel to the greatest rise of any large ridge of mountains, and so, in fact, we find them."

(Phil. Trans. 1760.)

And this system of layers or strata not only marks the arrangement of the great masses of which our earth is composed, but it is that of the very rocks themselves. It is to us attended with many advantages, such as the formation of springs,—the constitution of soils,—which last is that alluded to by Dr. Paris, On the Soil of Cornwall. "The phenomenon of stratification, which is so well characterized in clay slate, I have often regarded as a wise provision of nature to facilitate its decomposition, and to admit the descent of the roots of trees: and this idea is further strengthened when we discover that this structure is almost entirely confined to secondary rocks, whose situation and nature render them capable of cultivation: they are all, for instance, resolved into gently undulating hills, and by further decomposition they form rich and fertile soils. Primitive formations, on the contrary, which possess no such structure, disintegrate into rugged piles, whose declivities are too steep to admit the accumulations of soil, and cannot, therefore, ever constitute the habitable parts of the globe; and, as far as our geological knowledge will allow us to generalize, it would appear that primitive rocks are accumulated towards the poles, whereas the great mass of secondary formations is found to occupy the middle and southern latitudes, principally between the 30th and 55th degrees, which constitute a portion of the globe eminently calculated for the abode of men, and the animals which are subservient to his wants and comforts."

The farmer must not imagine, as he pursues his researches in this very interesting science, that he will find a great variety of earthly substances in the different, often-varying strata of the earth; "for," as Mr. Brande says very truly, "siliceous, calcareous, and argillaceous substances, either pure, or nearly so, or in a state of mixture, or loosely and indefinitely blended, rather than in strict chemical combination, constitute a very large relative proportion of those rocky masses, or scattered or comminuted substances, which form, or have formed, the most exterior constituents of our planet, and of these, considered in the abstract, the chemical and mineralogical history is soon told." Of that brief history, however, it will be well for the farmer to have a general knowledge. Davy, who saw very clearly the importance of the science to practical agricul-

ture, described them with a view to assist the farmer in his tillage operations.

The formation of a soil from the different strata by natural causes is also well described by the same great chemist. "It is easy," he says, "to form an idea of the manner in which rocks are converted into soils by referring to the instance of soft granite or porcelan granite. This substance consists of three ingredients, quartz, feldspar, and mica. The quartz is almost pure siliceous earth, in a crystalline form. The feldspar and mica are compound substances: both contain silica, alumina, and oxide of iron; in the feldspar there is usually lime and potassa; in the mica, lime and magnesia.

"When a granitic rock of this kind has been long exposed to the influence of air and water, the lime and the potassa contained in its constituent parts are acted upon by water or carbonic acid; and the oxide of iron, which is almost always in its least oxidized state, tends to combine with more oxygen; the consequence is, the feldspar decomposes, and like-wise the mica, but more slowly. The feldspar, which is, as it were, the cement of the stone, forms a fine clay. The mica partially decomposes, mixes with it as sand, and the undecomposed quartz appear as gravel or sand of different degrees of fineness.

"As soon as the smallest layer of earth is formed on the surface of a rock, the seed of lichens, mosses, and other imperfect vegetables which are constantly floating in the atmosphere, and which have made it their resting-place, begin to vegetate. Their death, decomposition, and decay, afford a certain quantity of organizable matter, which mixes with the earthy materials of the rock; in this improved soil more perfect plants are capable of subsisting; these, in their turn, absorb nourishment from water and the atmosphere, and, after perishing, afford new materials to those already provided. The decomposition of the rock still continues, and, at length, by such slow and gradual processes, a soil is formed in which even forest trees can fix their roots, and which is fitted to reward the labour of the cultivator." (Ibid. p. 183.)

That the physical formations of the soil influences to a considerable degree its relations to a fertilizing supply of moisture, was thus noticed by Dr. Paris when addressing a Cornish Agricultural Society:—"There is a popular adage well known to all the members of this society, that 'the land of Cornwall will bear a shower every week-day, and two upon a Sunday,'—the fact is, that the shallowness of the soil, and the nature of its rocky substratum, render a constant supply of moisture indispensable; and here we cannot avoid admiring the beautiful contrivance of nature in connecting the wants and necessities of the different parts of the creation with the power and means of supplying them; thus, in rocky countries like Cornwall, where the soil is necessarily greedy of moisture, the very cause which creates this want is of itself capable of supplying it; for the rocks elevated above the surface solicit a tribute from every passing shower, while in alluvial and champaign
GEOLOGY.

countries, where the soil is deep and rich, and consequently requires less moisture, the clouds float undisturbed over the plains, and the country frequently enjoys that long and uninterrupted series of dry weather which is so congenial to it. As a general rule it may be stated, that to obtain the greatest fertility the proportion of siliceous sand in a soil ought to increase in proportion to the quantity of rain that falls, or rather perhaps to the frequency of its recurrence; for one of the effects of silex is to diminish in the soil its power of absorbing moisture; we accordingly find that in the rainy climate of Turin the most prolific soil has from 77 to 80 per cent, of siliceous earth, and from 9 to 14 of calcareous, whereas, in the neighbourhood of Paris, where there is much less rain, the silex bears only the proportion of from 26 to 50 per cent. in the most fertile parts; and I have found some of the most productive corn lands in the parish of St. Burian to contain as much as 70 per cent, of that earth.

See EARTHS, THEIR USE TO VEGETATION.

It will, perhaps, considerably assist the cultivator in his examination of the different geological formations to which he may have to direct his attention, if we examine the chemical composition of a few of the stones and other substances of which rocks are chiefly formed.

Common clay is merely a mixture of alumina with silica, in endless proportions. The alumina is in the form of a very impalpable powder; but the silica, says Dr. Thomson, is almost always in small grains, large enough to be distinguished by the eye. Clay, therefore, exhibits the characters of alumina, and not of silica, even when this last ingredient predominates. Besides alumina and silica, clay often contains carbonate of lime (chalk), carbonate of magnesia, carbonate of baryta, oxide of iron, &c. (Chem. vol. iii. p. 341.)

Loam may be regarded as a very impure potter's clay united with iron, ochre, and mica.

Common Mica.—This stone is composed, according to the analysis of M. Klaproth, of:

<table>
<thead>
<tr>
<th>Substance</th>
<th>Parts</th>

</table>

The cultivator, therefore, must take it as an axiom in his geological observations, that the earthy composition of the surface soil almost always partakes of the nature of the rock or subsoil on which it immediately rests, and from which, in fact, it has been generally thus formed, in the progress of time, by various external agencies. Alluvial soils, perhaps, are the most extensive exceptions to this remark, for they are formed commonly of the materials of different strata, brought from various distances by the flood waters, and mingled together, often in very confused, yet most commonly in very fertile proportions. (See ALlUYIEN.) Of this description of soil there are in England many valuable tracts, such as that extending from Lynn, through Lincolnshire to the Humber, and thence to Bridlington. Both sides of the valley of the Thames, about Sandwich in Kent, Romney Marsh, between Bristol and Bridgewater, and Liverpool and Lancaster, and on the banks of the rivers Firth and Tay in Scotland. “This kind of soil,” says Mr. Morton, “is always fertile, free in its nature, and easily cultivated; is fitted for the production of every variety of crop, which it brings to the highest perfection, and produces in the greatest abundance. This formation is perfectly dry. About one-half of all the alluvial accumulations may be in tillage, and the remaining half in meadow and pasture land.” (On Soils, p. 10.)

Diluvium is the geological name for those masses of soil, composed of sand, gravel, &c., which are found in many places, covering some of the older formations. It is of various composition: when it is found resting on the tertiary and chalk formations, it is usually composed of red clay and rounded flints. In Dorsetshire the diluvium is commonly composed of a mixture of sand and gravelly flints. “Most of this soil,” says Mr. Morton, “is in arable culture, and produces turnips, barley, oats, wheat, clover; and, when under proper management, it becomes a useful soil. The tenacious clay gravel is expensive in the cultivation, as it is most difficult to work, except between wet and dry. The greatest improvement which has been made in this soil is by the application of chalk.” The larger portion of Suffolk and Norfolk is composed of a diluvium sand, resting on chalk or marl. This district is very level: it extends from Sudbury to Bungay and Cromer, from Southwold to Shelford, and from Swaffham to Yarmouth. Resting as it does on a calcareous substratum, the excellent cultivators of this district have gradually and permanently improved the soil by bringing the chalk or marl to the surface, and spreading it over the land at the rate of about 100 cubic yards per acre; in this way mere rabbit warrens of blowing sands have been improved so as to yield excellent crops of corn, and rentals have been in this way raised from a few pence to 20s. per acre.

Peat Soils.—These abound in many portions of the United Kingdom. Their best mode of improvement is, usually, by mixing them with the earths. See PEAT SOILS.

The Chalk Formation.—This formation, very common in England, but which does not exist in the limits of the United States, is divided by geologists into two divisions, the upper and the lower chalk: the upper abounds in flints, which are absent from the lower formation. Chalk is chiefly carbonate of lime, with some small portions of alumina, iron, and silica. “The water which comes from below the lower chalk,” says Mr. Morton, “is pure and limpid, and delicious to drink. It contains carbonate of lime, and is the best quality for watering meadows; hence the best water meadows are in the chalk valleys.” The soil of the chalk formation is composed of chalk and flint in various proportions. These soils are materially improved by a mixture with those of the green sandstone formation, and by enclosing.
into much smaller fields than those into which they are present generally divided.

*Green Sand Formation.*—This formation is found under the chalk. It is formed of a variety of beds: the upper beds near the chalk have a thin, or grayish, yellow or brown, the lower beds, which are commonly much thicker, vary in colour, from yellow to brown and red. It is composed of silicious sand, mixed with mica and chlorite. "The means of permanently improving this soil," says Mr. Morton, "after it is drained and enclosed (if for pasture), are so immediately within the reach of the farmer, that he can at little comparative expense improve its texture, and permanently increase its productiveness, by chalky or chalk marl, on the one hand, and the oak or clunch clay, on the other; but even without the application of these substances, deep or double ploughing or trenching has the effect of deepening the soil, and increasing its capability. When mixed with the chalk marl above it, it has the power of receiving and transmitting moisture more freely, and is neither so easily injured by wet weather, nor by excessive droughts, as other soils are." *(On Soils, p. 43.)*

Gault has commonly a bluish or gray aspect, and its geological position is in the centre of the green sand formation: the two greatest deposits of it, in England, are in the Vale of White Horse, in Berkshire, and in the counties of Cambridge and Huntingdon. Its found at South Marston, in Wiltshire, at Wantage, Thame, through Bedfordshire to Caxton and St. Ives.

Before the year 1807, although mineralogy had received some attention in the United States, little or nothing had been done towards ascertaining its geological features. At that time William Maclure commenced the task, and single-handed, made a progress which reflects the highest credit upon his memory, for he developed the leading characteristics of the rock formations, in doing which, he crossed the Alleghany mountains in fifty places. The state geological surveys which have been carried on for several years past, and are still prosecuted, seem to be enterprises peculiarly American, having preceded those regularly undertaken in any other country. The annual reports of these surveys have dwelt much upon economical geology, and placed an immense mass of minute and accurate information before the public, which cannot fail to be profitable to agriculture and other useful objects. North Carolina has the honour of having first directed a survey of her territory, a duty performed by Prof. Olmsted, whose reports were made in 1824, 1825; since then, South Carolina has been geologically explored by Prof. Vanuxum. These two Southern States were succeeded by Massachusetts, the last report of which, by Prof. Hitchcock, was made in 1837. Tennessee has been explored by Prof. Troost, Maryland by Prof. Ducatell; New Jersey and Pennsylvania by Prof. H. D. Rogers; Delaware by Prof. J. C. Booth; New York by the late Hon. Prof. Vanuxum, Mather, Emmons, and Mr. James Hall; Virginia by Prof. William B. Rogers; Maine, Rhode Island, and New Hampshire, by Dr. Charles T. Jackson; Connecticut by Dr. J. G. Percival and Prof. C. U. Shepard; Ohio by Prof. Mather, assisted by Dr. S. P. Hildreth, and Prof. Locke, Briggs, and Foster; Michigan by Prof. D. Houghton; Indiana by Dr. D. D. Owen; and Georgia by Mr. J. R. Cottin. It thus appears that within the last 16 or 17 years, surveys have been commenced, and most of them completed, in 19 states and two territories of the Union, embracing an area of nearly 700,000 square miles, and that for some years past not less than 25 principal geologists, and 40 assistant geologists, have been almost constantly engaged under the patronage of the state governments, in the examination of the various parts of the Union. The British provinces of New Brunswick and Nova Scotia have also been geologically examined by Dr. Gessner, whilst the exploration of Canada has been commenced under the superintendence of Mr. Logan. Much of the material thus amassed cannot fail to be of high interest in an agricultural point of view, as pointing the situation and exact value of soils, and the invaluable beds of mineral fertilizers, in the form of lime, marl, green sand or silicate of potash, &c., &c.

From such facts as these the farmer will readily perceive that the science of geology is not without its material and extensive value to the tiller of the earth. It enables him at least to cultivate his soils on solid data, to avoid the adoption of idle and fruitless modes of cultivation, to pursue that which the situation of the strata he tenants determines to be the best. It is no reason for the neglect of its assistance that other sciences can perhaps do more for the farmer; and even the objection, though very common, amounts, in fact, to an admission that geology is a science capable of rendering services to agriculture. *(Brand's Lect. on Geology; Morton on Soils; Davey's Elem. Ag. Chem.; Paris on the Soils of Cornwall; J. F. Johnston's Lex. Chem. and Geol.; Prof. H. D. Rogers's Geological Surveys of Pennsylvania and New Jersey; Prof. C. J. Booth's Survey of Delaware; Professor Jackson's Survey of Massachusetts; Geological Survey of New York; Dr. Ruffin's Survey of North Carolina, &c., &c.)*

**GEOMETERS.** A species of caterpillar.

See *Span-worns.*

**GEORGIA BARK (Pinémuca porbena).** "This tree," says Michaux, the younger, "still more interesting by the properties of its bark; than by the elegance of its flowers and of its foliage, is indigenous to the most southern parts of the United States: probably it grows also in the two Floridas and in Lower Louisiana. My father found it for the first time in 1791 on the banks of the St. Mary. He carried seeds and young plants to Charleston, and planted them in a garden which he possessed near that city. Though intrusted to an ungrateful soil, they succeeded so well, that in 1807 I found several of them 25 feet high, and 7 or 8 inches in diameter; which proves that the vegetation of this tree does not require a very warm climate, nor a very substantial soil.

"With a great affinity to the *cinchona* which yields the Peruvian bark, my father discerned in the Georgia bark sufficient differences, to distinguish it as a new genus. In testimony of his gratitude and respect, he consecrated it to Charles Cotesworth Pinckney, an enlightened
patron of the arts and sciences, from whom my father and myself, during our residence in
South Carolina, received multiplied proofs of
benevolence and esteem.

"The Georgia bark is a low tree, dividing
itself into numerous branches, and rarely ex-
ceeding the height of 25 feet, and the diameter
of 6 or 8 inches at the base. A cool and shady
shrub is nearly the most favourable to its
growth. Its leaves are opposite, 4 or 5 inches
long, of a light green colour, and downy un-
derneath, as are also the shoots to which they
are attached. The flowers, which are white
with longitudinal rose-coloured stripes, are
pretty large, and are collected in beautiful
pinnacles at the extremity of the branches.
Each flower is accompanied by a floral leaf,
bordered with rose-colour near the upper edge.
The capsules are round, compressed in the
middle, and stored with a great number of
small winged seeds.

"The wood of the Georgia bark is soft, and
unfit for use in the arts; but its inner bark is
extremely bitter, and appears to partake of the
febrifuge virtues of the cinchona, for the inha-
bitants of the southern parts of Georgia employ
it successfully in the intermittent fevers which,
during the latter part of summer and autumn,
prevail in the Southern States. A handful of
the bark is boiled in a quart of water till the
liquid is reduced one-half, and the infusion
is administered to the sick. From the proper-
ties of its bark the pines have taken the name of
Georgia bark. The tree which produces it so
nearly resembles the Peruvian vegetable, that
some botanists have included them in the same
genus.

GEORGIA PITCH PINE, or long-leaved
pines. See Fir.

GERANIUM. From a Greek word signifi-
cying a crane, the beaked fruit bearing some
resemblance to a crane's bill. The varieties
of this genus of beautiful plants cultivated
are very numerous, but all are tender. The
common scarlet geranium is the hardiest shrub,
and the handsomest. It looks beautiful plant-
ed in lawns and gardens, and grows extremely
busily and handsome in a fine light soil.
Cuttings strike so readily, that the old shrub may
die every fall, and be renewed every summer
from the frame. The best plants come from
seeds sown in July: the seedlings must be
kept warm, but not forced. The scarlet ger-
nium thrives well through the winter, if placed
in the house, free from damp and stagnant air.
It is very ornamental during summer and autumn.
Sweet's Geraniums, and other works on the
subject, may be consulted with advantage by
those desirous of further information as to the
best varieties of geranium, &c.

The species of geranium family most fre-
quently found growing wild in the United States
are, 1st. The maculatum, or spotted geranium,
known by a common stamens, cross-foot and
spotted stamens's bill. It is perennial, and frequents
fence-rows, woodlands, and meadows, flower-
ing in May and June in Pennsylvania. The
root is astringent, and has been found service-
able in the treatment of dysentery, diarrhoea,
and hemorrhage. 2. Carolinian Geriant, not so
common as the former. Three or four addi-
tional species are enumerated in the United
States. (Darlington's Flor. Cestrica.)

GERMANER (Mecurium). Of this genus of
perennial plants there are three wild species
common to England. 1. The wood german-
er, or wood sage (T. scorodonia), which is
found in great profusion inappy places and
woods, on a sandy soil, and flowers in
the month of July. The root is creeping;
the stem reaches to two feet high, is leafy,
hairy, acutely quadrangular. The leaves are
deeep green, wrinkled, hairy, copiously ser-
rated; the flowers are pale yellow, in clusters,
terminal, and axillary; corolla pale yellow,
middle lobe concave and hairy. The whole
plant is glutinous, and has a bitter taste, with
an agreeable aromatic scent, much resembling
that of hops, for which it is said to be no bad
substitute in making beer. It is used in the
island of Jersey in brewing.

2. The water germander (T. scoridum) is
less common, and grows in low, wet meadows
and damp marshy situations, and produces
puerilus flowers in July and August. The
herb is downy; the leaves are very bitter, and
somewhat pungent, with a strong garlic-like
odour. The root is creeping; the stem recum-
ent, branching, with obtuse, horny, scarcely
serrated sessile leaves, an inch long. Flowers
two, from axilla of each leaf. Corolla pale
dull purple; middle lobe flatish, with two
spots. It is eaten by sheep and goats, but re-
fused by horses, hogs, and cows, though the
latter will eat it when impelled by hunger;
but it spoils the flavour of their milk.

3. The common wall germander (T. chama-
drys) is found on the borders of cornfields that
are remote from houses, or old ruined build-
ings and stony banks: it produces crimson or
reddish purple flowers, which blow in the
month of June or July. Root creeping; stems
erect, bushy, leafy, hairy; angles rounded;
leaves dark green, tapering, fringed, entire at
the base. Flowers have the central lobe
rounded, a little concave; the lateral lobes and
the tube hairy. The whole herb is very bitter,
with a weak aromatic flavour, and was for-
merly used to remove obstructed secretions, to
promote expectoration, perspiration, &c. (Eng.
Flor. vol. iii. p. 69.) In the United States there
is a species of germander called, in the Middle
States, Wood Sage (T. Canadensis). The root
is perennial, and it frequents fence rows and
low shaded grounds. One other species of this
plant has been found on the Rocky Mountains.
(Flor. Cestrica.)

GERMANY. The agriculture of a district
so extensive as that of Germany, naturally
varies with the nature of the climate and the
degree of knowledge possessed by the inhabi-
tants of the numerous and extensive provinces
of which the empire is composed. In the
Mecklenburgs, or that portion of Germany
bounded by the Baltic on the north, according
to Mr. J. S. Carr, "from north to south there is
a ridge of elevated sandy land (the same
which may be traced from the Bannat in Hun-
gary to Jutland in Denmark) varying from 10
to 20 miles in breadth, affording miserable
crops of corn and worse pasture; but the soil
improves on both sides towards the Elbe and
the Baltic, where fine districts of rich loams and clays are managed with considerable plodding industry." The farms in northern Germany vary in size from 50 to 60 acres, cultivated by peasants, to 300 and even 2000 in the hands of the farmers and proprietors. The number of cows kept by the farmers are often 300 and 400, and they are sensibly alive to the advantages of sheltering stock in winter. Their sheep-houses are commonly large enough to hold 5000 head. They usually harvest all their corn in barrows. Their agricultural implements are defective: for instance, they use generally, instead of a plough, an instrument called a haken, which is exactly similar to one used by the Roman farmers. Their harrows have commonly wooden teeth, and are worked with five horses, in a very bungling manner. They often break up their pastures with this clumsy instrument in summer, expose it to the frosts of the following winter, spread over it their dung, and in the following July sow broadcast rape seed. This they dress with 100 lbs. of gypsum dust per acre, in the following spring, and in July the seed is ripe, which is then trodden out by horses on large canvass sheets in the field.

"The oil of this seed, when purified, is without smell, gives a brilliant, clear-burning flame, and is universally used all over Germany, in the saloon and the cottage." This crop escapes the manifold contingencies of slugs, caterpillars, turnip fly, and beetles, it is a very remunerative one, worth from 10L to 20L per acre. The improved rotations now commonly followed in Germany, are 1. Fallow, well dugged. 2. Rape. 3. Wheat. 4. Barley. 5. Peas (with light dungen). 6. Rye. 7. Oats, sown down with rye or Timothy grass, and red clover, "which, as well as the peas, is gypsumed with great effect before the dew has left the plant of a May morning." The clover, after being twice mown, is left 2 years longer for pasture. Marl, at the rate of 164 cubic feet per acre, is much used, and is the beginning, in many places, of all improvements. The haken is worked by oxen. The merino breed of sheep is now extensively cultivated in the Mecklenburgs and in Saxony. There is little else to be noticed in their live-stock. The farm servants are commonly lodged and fed in the house, and are paid from 5L to 6L per annum. The married labourers have a free house and firing, the keep of a cow, and about one rood of garden, and twice as much potato land. The average rent of wheat and barley lands is about 18s. per acre. Manures of all kinds are preserved with much care; and they show a wisdom in the collection of night-soil and that of the sewerage of their towns, which it would be well to imitate in England. These manures are extensively used for their vineyards in several parts of Germany. The following account of them is taken from a paper by Dr. Granville:

"In most of the cities of the second order, and the smaller capitals, night-soil is a source of profit, first to the householder, next to a middleman, and thirdly to the farmer, who is the last purchaser, and employs it. In all the towns of the Grand Duchy of Baden, of the kingdom of Württemburg, of Bavaria (except Munich and Würzburg), of the province of Salzburg, of Bohemia (except Prague), of Saxony (except Dresden), in some of the minor cities of Prussia, in all the confederated principalities, in all the cities on both banks of the Rhine, particularly Strasburg, Mayence, Coblenz, Bonn, Cologne, Dusseldorf, Nimeguen, &c., the householder disposes of the contents of his cesspool for a certain sum of money, besides getting the operation of emptying it performed gratuitously. By comparing the returns of the different prices paid in those cities for the commodity in question, one year with another, and equalizing them by an average price, founded on positive data, which I possess, the inhabitants appear to be benefited to the amount of 4 francs a head yearly, and the middle-man to at least 40 per cent. more on the sum he pays to the original seller. I will cite Strasburg as an example, since most of the other cities of the same extent (on the Rhine, and in many parts of Germany), and a few cities ever larger, presented the strongest analogy to the case I have selected. At Strasburg a company of middlemen engage to empty the cesspools, of which every house has at least two (built air and water tight), once a year for nothing, and pays, moreover, 6 francs per charrette, containing 90 buckets, of the capacity of 4 gallons each. This quantity the company sells afterwards to the farmers for ten francs. (The capacity of the charrette being to that of a ton, as 28,775 ounces are to 35,840, it follows that the price of a ton at Strasburg in 1842 would be 10 francs.) As there are 14,000 houses in Strasburg, 10,000 of which have cesspools, affording the soil in question (which is always semi-liquid), supposing the latter to be emptied only once a year, and to furnish each 3 charrettes only, at six francs, we have 10,000 X 6 X 3 = 180,000 francs, which the company pays yearly to the inhabitants of a town having a population of 70,000 souls. But as the company resells to the farmer the said soil for nourishing purposes, at ten francs per charrette, it follows that this article of traffic produces yearly at Strasburg 300,000 francs, or just about 4½ francs per franc of the average sum, therefore, for each inhabitant of a city, where the mixed contents of cesspools are sold for their benefit, which I have assumed may be adopted with safety, as founded on fact. (Journ. Roy. Agr. Soc. vol. i. p. 124—371; Rep. Thames Improv. 17.)

GERMEN (Lat. a bud). In botany, the organ commonly called the ovarium.

GERMINATION (Lat. germinare). The process by which a plant is produced from a seed. It is, in truth, the springing into life of a new individual. The phenomena of germination are best observed in dicotyledonous seeds; such, for instance, as the bean, pea, lupin, &c. These seeds consist of two lobes or cotyledons, enveloped in a common membrane; when this is removed a small projecting body is seen, which is that part of the germ which subsequently becomes the root, and is termed the radicle; the other portion of the germ is seen on carefully separating the cotyledons, and is termed the plumula; it afterwards forms the stem.
and leaves. When the ripe seed is removed from the parent plant it gradually dries, and may be kept often for an indefinite period, without undergoing any change; but if placed under circumstances favourable to its germina-
tion, it soon begins to grow: these requisite circumstances are a due temperature, mois-
ture, and the presence of air. The most fa-
vourable temperature is between 60° and 80°; at the freezing point none of the most perfect seeds vegetate, and at temperatures above 100° the young germ is usually injured. No seed will grow without moisture: water is at first absorbed by the pores of the external cover-
ing, and decomposed; the seed gradually swells, its membranes burst, and the germ ex-
pands. The root is at first most rapidly de-
veloped, the materials for its growth being
derived from the cotyledons; and when it shoots out its fibres or rootlets, these absorb nourishment from the soil, and the plumula is de-
veloped in a mass of primary tissue, many di-

tinuous to the root, and expanding into stem and
leaves. For this growth the presence of air is
requisite; if it be carefully excluded, though there be heat and moisture, yet the seed will not
vegetate. Hence it is that seeds buried very deep in the earth or in a stiff clay, remain
inert; but on admission of air, by turning up the
soil, begin to vegetate. From experiments
which have been made upon the germination
of seeds in confined atmospheres, it appears
that the oxygen set free by the decomposition
of water, combines with a portion of the car-
bon of the seed, and carries it off in the form
of carbonic acid, and that the consequence of
this is the conversion of part of the albumen
and starch of the cotyledons into gum and
sugar; so that most seeds, as we see in the
conversion of barley into malt, become sweet
during germination. Light is injurious to the
growth of the seed. It is, therefore, obvious
that the different requisites for germination are
attained by placing a seed under the surface
of the soil, where, warmed by the sun's rays,
and evagated by the humidity of the atmos-
phere, it is excluded from light, but the air has
access to it.

Oxygen is an essential agent in the process
of germination, and without it seed will not
germinate, a fact which has been demonstrated
by placing seeds in vacuo, and in nitrogen, hy-
drogen, and carbonic acid. But, as in animal
life, too much oxygen is hurtful: it abstracts
the carbon too rapidly, overstimulates, and
causes feebleness of growth to the infant plant.

When the young plant is protected by the cotyle-
dons, not converted into leaves, rot away, and
the process of nutrition is carried on by the
root and leaves: the principal nourishment
is taken up from the soil by the root, and chiefly
by its small and extreme fibres; so that when
these are injured or torn, as by careless trans-
plantation, the plant or tree generally dies.

The matters absorbed, consisting of water
holding small portions of saline substances,
and of organic matter in solution, become the
sap of the plant; and this is propelled upwards
in the vessels of the stem, or of the outer layer
of the wood, into the leaves; here it is exposed
to the agency of air and of light; moisture,
and occasionally carbonic acid, is transpired.
But the leaves also at times absorb moisture,
and during the influence of light they decom-
pose the carbonic acid, and retaining the car-on, evolve oxygen; the sap thus becomes
modified in its composition, and the charac-
teristic proximate principles of the vegetable
are formed. These return in appropriate ves-
sels from the leaves chiefly to the inner bark,
where we accordingly find the accumulation of
the peculiar product of the plant; they also
enable it annually to form a new layer of wood.
Hence it is that the transverse section of the
wood exhibits as many distinct zones as the
tree is years old. We are ignorant of the
causes of this ascent of the sap; but that it
does follow the cause which has been stated is
proved by the operation which gardeners call
ringing, and which they sometimes resort to, to
make a barren branch bear flowers and fruit.

It consists in cutting out and removing a cir-
cular ring of vessels to prevent the ascent of
the sap by the descending vessels, which at
first ooze copiously, but afterwards the wound
heals, and the juices are accumulated in all
parts above the extirpated ring, producing
tumefaction in the limb, and often inducing a
crop of flowers and fruit, or causing those to
appear earlier than on the uncut branches.

If a tree be wounded so as to cut into the
central portions of the wood, or the outer layer
of new wood, the flow of ascending sap is
then seen to take place upon the lower section,
where the vessels are that carry it up to the
leaves; and the flow of descending proper
juice is principally confined to the upper sec-
tion of the inner bark, from which, after a
time, new bark is produced, and the parts are
again united. To return to the process of
germination, every part of the seed is not es-
tential, nor the whole of the parts. Kidney
beans will germinate with only one cotyledon:
and oaks, also, germinate in the same state;
gourds have been robbed of the radicle and
also the plumule, as they shoot forth, and yet
germinate; but proceeded; but the plants
produced in all these cases were small, deli-
cate, and never come to perfection.

GESTATION. The gestatory term in quad-
rupeds is much regulated by their bulk. In
the elephant it is about 20 months, in the camel
between 11 and 12, in the mare and ass the
same. According to the observations of M.
Teissier of Paris, in 582 mares, which copu-
lated but once, the shortest period was 287
days, and the longest 419; making an aver-
287...
unacquainted with the proper age for reproduction, the duration of the power of reproduction, and other conditions even of the domesticated animals. It cannot, therefore, but be interesting to find in the following table the results of observations made on this subject by the best ancient and modern naturalists.

</tbody>
</table>

Some of these results do not altogether coincide with the results of observations in England, where, for example, July, the season of copulation for the cow, is considered too late. That period would produce late calves in the following year. November is stated to be the best season for the ewe; for the black-faced ewe it is, but for the Leicester, and, in many situations, for the Cheviot ewe, it is a month too late. The duration of the power of reproduction accords with our experience as respects the mare and stallion; but 13 years of age for the cow, and 8 for the bull, is too young a period for old age in them, fine animals of both sexes, of a valuable breed, having been kept in a useful state to a much greater age. I have seen a short-horn bull in use at 13 years, and a cow of the same breed bearing calves at 18; but if the ages of 8 and 13 respectively refer to the usual time bulls and cows are kept for use, the statement is not far from the truth.

From some carefully collected and very extensive notes made by Lord Spencer on the periods of gestation of 764 cows, it resulted that the shortest period of gestation when a live calf was produced was 220 days, and the longest 313 days, but he was not able to rear any calf produced at an earlier period than 242 days. From the result of his experiments it appears that 314 cows calved before the 284th day, and 310 calved after the 286th; so that the probable period of gestation ought to be considered 284 or 285 days. The experiments of M. Teissier on the gestation of cows, are recorded to have given the following results:—

21 calves between the 240th and 267th day, the mean time being 251; 544 = 270th and 299th = 281; 40 = 270th and 321st = 821.

In most cases, therefore, between nine and ten months may be assumed as the usual period; though, with a bull-calf, the cow has been generally observed to go about 41 weeks, and a few days less with a female. Any calf produced at an earlier period than 260 days must be considered decidedly premature, and any period of gestation exceeding 300 days must also be considered irregular; but in this latter case, the health of the produce is not affected. I will conclude this article with the remarks of Mr. C. Hilliard, of Northampton, who states that the period of gestation of a cow is 284 days, or, as it is said, 9 calendar months and 9 days; the ewe 20 weeks; the sow 16 weeks; the mare 11 months. The well-bred cattle of the present time appear to me to bring forth twins more frequently than the cattle did 50 years ago. The males of all animals, hares excepted, are larger than the females. Castrated male cattle become larger beasts than entire males. (Blaine's Ency. pp. 205, 281; Quart. Journ. of Agr. vol. x. p. 287.)

GILL. A small valley, connected with a stream and some woodiness. Also a rivulet, or small brook. It is likewise a provincial name in some districts for a pair of timber wheels.

GILTS. A provincial term applied to young female pigs, whether open or spayed.

GINGER, WILD. (Asarum, Asarabacca, Indian ginger). This genus of herbaceous plants are small and unobstrusive. Botanists enumerate three species as found in the United States. That called Canada snake root (J. Canadense), very closely resembles the European asarabacca, and is met with in old woods from Canada to the Carolinas. It has only two round, flat, and kidney-shaped leaves with naked stalks, which, on plucking the plant are found connected below, with an obscure flower in their fork, buried under the decayed leaves. It flowers from May to July. The root is creeping.
fleshy, somewhat jointed, and has an agreeable aromatic taste, intermediate between that of ginger and the Virginia snake root. Hence its popular names. As a warm stimulant and diaphoretic it is much praised, being given in the form of tea or powder; and as a substitute for ginger, in common domestic use, I know of no indigenous article, says Dr. Bigelow, which promises so fairly as this. It does not possess the very active emetic, cathartic, and sterility powers of the European asarum. The other American species are the A. Virginicum, and A. trifolium.

GLIESN (Panax quingfofolium, five-leaved panax). This American plant, which has great commercial importance, has a perennial root, which sends up annually a smooth, round stem, about a foot in height, dividing at the summit into three leafstalks, each of which supports a compound leaf, consisting of five, or more rarely of three or seven petiole, oblong, obovate, acuminate, serrate leaflets. The leaves are small, greenish, and arranged in a simple umbel, supported by a peduncle, which rises from the top of the stem in the centre of the petioles. The fruit consists of kidney-shaped, scarlet berries, crowned with the styles and calyx, and containing two, and sometimes three seeds. The root is fleshy, somewhat spindle-shaped, from 1 to 3 inches long, about as thick as the little finger, and terminated by several slender fibres. Frequently there are two portions, sometimes three or more, connected at their upper extremity, and bearing a supposed though very remote resemblance to the human figure, from which circumstance it is said that the Chinese name ginseng originated. When dried, the root is yellowish white, and wrinkled externally, and within consists of a hard, hornlike substance, surrounded by a whitish, softer, cortical portion. It has a feeble odor, and a sweet, slightly aromatic taste, somewhat analogous to that of liquorice root. It has not been accurately analyzed, but is said to be rich in gum and starch.

The plant grows in the hilly regions of the Northern, Middle and Western States, and prefers the shelter of thick, shady woods. It is a native also of Chinese Tartary. The root is the part employed. This is collected in considerable quantities in Ohio and Western Virginia, and brought to Philadelphia and other cities on the sea-board for the purpose of exportation to China, where it is highly valued. While supplied exclusively from their own native sources, which furnished the root only in small quantities, the Chinese entertained the most extravagant notions of its virtues, considering it as a remedy for all diseases, and as possessing almost miraculous powers in preserving health, invigorating the system, and prolonging life. It is said to have been worth its weight in gold at Pekin; and the first shipments made from North America to Canton, after the discovery of the root in this country, were attended with enormous profits. But the subsequent abundance of supply has greatly diminished its value, and though it still occasionally forms a part of the investments for Canton, it has become an object of less importance than formerly.

The following statement shows the value of the ginseng exported from the United States for seven years ending the 30th September, 1841: viz. 1834, $70,205; 1835, $94,970; 1836, $211,405; 1837, $109,368; 1838, $36,622; 1839, $118, 904; 1840, $22,728; 1841, $437,245.

Medical Properties and Uses.—The extraordinary medical virtues formerly ascribed to ginseng, had no other existence than in the imaginations of the Chinese. It is little more than a demulcent; and in this country is not employed as a medicine. Some persons, however, are in the habit of chewing it, having acquired a relish for its taste; and it is chiefly to supply the wants of these that it is kept in the shops. (U. S. Dispensatory.)

There is another species of ginseng indigenous to the lower part of Pennsylvania and other sections of the United States, called the dwarf ginseng, or three-leaved panax (P. trifoliun). This has also a perennial root, a globose tuber about half an inch in diameter, which is farther deep in the ground. The stem grows 3 to 6 inches high, slender, minutely grooved, smooth, mostly of a tawny purple colour, divided at the summit into three petioles of half an inch to an inch long. Leaflets, generally three, but not uncommonly five, unequal, half an inch to two inches long, and ½ to ¾ of an inch wide, lance-oblong shape, rather acute. The flower is white and has five petals. The plant frequents shaded grounds, along rivulets, where it blooms in April. (Flora Cestirica.)

Professor Hooper describes a third species of ginseng (P. horridum), which is large, shrubby and prickly. This grows west of the Rocky Mountains.

GIPSEY-WORT, or WATER HORE-HOUND (Lycopus Europaeus). An herbaceous perennial plant, growing on the banks of clear ditches, pools, and rivers, on a sandy or gravelly soil, flowering in July or August. The root is creeping, stem two feet high, leaves numerous, oblong, acute, deeply serrated, often deeply pinnatifid. Flowers white, with purple dots. (Boyle's Pemb.)

GLANDER. A disease in horses, attended with a copious discharge of mucus from the nose. It is needless to endeavour to describe the various attempts which have been made to cure this almost invariably fatal disorder. But the farmer must avoid a common error of confusing ulceration of the membrane of the nose with glanders, for the symptoms are very similar. Blue vitriol (sulphate of copper) in thin gruel (one drachm doses) has been given in recent cases with occasional success. The nostrils may be washed with a solution of chloride of lime. The farmer will do well, as soon as he finds a horse attacked with this disease, to place him by himself, give him green food, and thoroughly whitewash the stable from which he is taken, for it is a most contagious disease.

GLASSWORT, JOINTED (Salicornia; from sal, salt, and corum, a horn). Of this genus of plants there are, in England, four indigenous species, which are found very common in salt marshes and muddy sea-shores that are frequently overflowed by the tide.

1. The common jointed glasswort, sea-grass,
or marsh samphire (S. herbacea), is an annual plant, with a small fibrous root, a bushy, green stem a foot high, with opposite branches; woody centre very tough. Flowers on numerous short-jointed spikes. The whole plant has a saline taste, abounding in salt juices, and is therefore devoured with avidity by all kinds of cattle; and it is a very wholesome food, especially for sheep. It is often pickled, as a substitute for the very different strongly aromatic rock samphire (Crithmum maritimum), to which it is for this purpose very little inferior.

Several other species of glass-wort are enumerated, three of which Mr. Nuttall gives as American, which, like the European, affords soda when burned, and are preserved in vinegar as a pickle.

Soda is yielded in large quantities by the ashes of the different species of Salticaria; and is in great request for manufacturing soap and glass: the best is imported from Spain, under the name of Borrax (of consequence, and tenacity will grow in any common soil, and are readily increased by divisions. Being natives of the sea-shore, the plants will thrive better if a little salt be occasionally sprinkled on the surface of the soil. (Willich's Dend. Emyx.)

GLOW-WORM (Lampyris noctiluca). This insect is remarkable for the light it emits during the night. This luminous appearance depends upon a phosphorescent fluid found at the lower extremity of the insect; which, by unfolding or contracting itself, can withdraw the fluid with pleasure; a power of contraction to the insect, as it is thus secured from the attacks of nocturnal birds. The light arises from a sac, which is diaphanous, and contains a secreted fluid consisting of albumen and phosphorus. Glow-worms are sometimes called St. John's worms, from appearing first as a common occurrence about the Feast of St. John the Baptist. The glow-worm is the perfect female of a winged beetle; the males fly about chiefly in autumn, and frequent the grassy plantations of juniper trees.

GLUE (Lat. gluten). is prepared from the chitinous parts of the horns, hoofs, &c. The refuse matter of the glue-makers, according to Mr. Miles, is an excellent manure for turnips.

GLUTEN (Lat.). The viscous elastic substance which remains when wheat flour is wrapt in a coarse cloth, and washed under a stream of water, so as to carry off the starch and soluble matters. Gluten, when pure, is inodorous, insipid, tenacious, adhesive, and elastic. It is insoluble in water, but soluble in hot alcohol. It is also soluble in a dilute solution of potash. When kept moist and warm, it ferments. Gluten exists in grains, and occasionally in other parts of vegetables; but it is a characteristic ingredient in wheat, giving wheat flour its particular toughness in the mouth, which particularly fits it for the manufacture of bread, and for viscous pastes, such as macaroni and vermicelli. There is generally more gluten in the wheat of warm climates than of cold; hence the excellence of that grown in the south of Europe for the manufactures just mentioned. Gluten seems also to constitute the essential part of yeast. Its uses as a varnish, a ground for paint, &c., pointed out by Cadet, likewise deserve attention. Gluten was discovered in 1742 by Becaria, an Italian philosopher, to whom we are indebted for the first analysis of wheat flour. The number of plants containing gluten is very considerable. Proust found it in acorns, chestnuts, rice, barley, rye, peas and beans, and in apples and quinces. He found it also in the leaves of the cabbage, cress, hemlock, borage, saffron, &c., and in the sedums; in the berries of the elder, the grape, &c.; in the petals of the rose, &c. Gluten has been shown to resemble albumen so closely that they can hardly be considered as distinct principles. Gluten contains nitrogen, and has, consequently, been called the vegeto-animal principle, on this account. It yields ammonia, when subjected to destructive distillation; and the vegetables which contain it give out a peculiar disagreeable odour during their putrefaction. M. Magendie, after feeding animals upon different kinds of food, stated that gelatine, fibrin, albumen, when taken singly, do not possess the power of nourishing animals for any length of time; they always die. The reverse is the case, however, with gluten, upon which animals thrive well and long.

GNATS (Culex, Linn.). A genus of insects comprising several species, which are well known by the severe punctures they inflict. The gnat most common in Europe is the C. pipiens, so named from the sound which it emits in its flight. The sting consists of 5 pieces of a straw; some of the pieces are simple lances; others are barbed, and act both as piercers and as siphons, to extract the blood from the wounds which they make. Gnats deposit their eggs, to the number of 200 by each female, on stagnant waters, where they are hatched into small grubs in the course of 2 or 3 days. On the sides are 4 small fins, by the aid of which the insect swims about, and swiftly dives to the bottom. The larva retains its form a fortnight or 3 weeks, when it is converted into the chrysalis, in which state it continues 3 or 4 days, floating on the surface of the water, till it assumes the form of the gnat. The most eminent remedies for their sting are olive oil, unsalted butter, or fresh hog's lad, thinly rubbed in. Gnats have occasionally appeared in such numbers as to form a cloud, almost darkening the air, as was the case in August, 1766, near Oxford. Spencer describes a similar flight of them in Ireland—

"As when a swarme of gnats at eventide, Out of the fennes of Allan doe arise, Their murmuring small trumpetsstonnd wide, Whiles in the air their clustering army flies, That as a cloud doth seem to dim the skies."—Fair Queen.

The mosquito of tropical climates is a species of the same genus as the gnat; and the latter is not less troublesome in some of our marshy districts than the mosquito in the West Indies. In the marsh land of Norfolk, the better classes are forced to have gauze curtains to keep them off during the night.

The species of gnat best known in America is a small, black fly, which swarms during the month of June, and is especially annoying to travellers, and the first inhabitants of new set-
GOATS.

There are three species of this genus enumerated by naturalists. 1. The wild goat (C. aegagrus); 2. The ibex (C. ibex) is a little larger than the last; 3. The domestic, of which these, the first is believed to be the original of the many varieties of the domestic goat.

The goat appears (says Prof. Low) to form the connecting link between the sheep on the one hand, and the antelope tribes on the other. Being the natural inhabitant of mountainous regions, it is, therefore, in wild, rocky countries that the goat is chiefly reared. Goats are stronger, more nimble, and less timid than sheep, and are more easily supported than any other animals, for there are few herbs which they do not relish: they will browse on hedges, shrubs, and plants, which are rejected by other animals; and it is well known they can eat with safety herbs (such as the hemlock, hbane, &c.) which would prove destructive to sheep and other animals. Goats are more hardy, and not liable to so many diseases as sheep. The goat is not well adapted to a country of enclosures, because it feeds upon the twigs of hedges, and escapes over the barriers intended to confine it. But where there are no young trees to be injured, they may browse at large on the mountains without expense; and in winter, when housed, they are easily supported on whins or furze, cabbage leaves, potato-peelings, and such worthless food.

Goats emit at all times a strong and disagreeable odour, named hircine, which, however, is not without its use, for if one of these animals be kept in a stable, it is affirmed that it will be an effectual preventative of the staggers, a nervous disorder which is often very fatal to horses. In Great Britain the cultivation of the goat is limited and partial. It is chiefly confined to the mountainous parts of Wales, the Highlands of Scotland, and to the little farms of the poorer peasants of Ireland, whose scanty possessions will not support a cow. The great objection there to the rearing of the goat, is the want of demand for its flesh, which is hard, and almost indigestible. Even the kid, whose flesh is known to be very delicate and nourishing, is held in no estimation: hence all the other properties of the goat are insufficient to render it an object of profitable production. But the goat, although it never can be valuable there as in the dry and rocky countries of the south of Europe, does not deserve that entire neglect with which it is treated. It arrives early at maturity, and is very prolific, bearing two and sometimes three kids at a birth. The period of gestation is five months. The female bears for six or seven years; the male should not be kept longer than five. In Portugal and some other countries the goat is used as a beast of draught for light burdens. The hair of the goat may be shorn, as it is of some value, making good linsey; that of the Welsh he-goat is in great request for making white wigs. Ropes are sometimes made from goats' hair, and are said to last much longer, when used in the water, than those made of hemp. Candles are manufactured from their fat, which, in whiteness and quality, are stated to be superior to those of wax; their horns afford excellent handles for knives and forks; and the skin, especially that of the kid, is in demand for gloves and other purposes.

Goats' milk is slightly sweeter, nuttier, and colder, and less apt to curdle on the stomach than that of the cow: it forms an excellent substitute for that of asses. When yielding milk the goat will give, for several months, at the average of two quarts per day. Mr. Pringle of Kent, in his Essay "on Cottage Management" (Gard. Mag. vol.5.), informs us that two milch goats are equivalent to one small Shetland cow. Cheese prepared from goats' milk is much esteemed in mountainous countries after it has been kept a proper age. (Low's Pract. Agr. and Breeds of Dom. Animals; Willett's Dom. Enq.)

GOAT'S-BEARD (Tragopogon). Of this common pasture-weed there are two species. 1. The yellow goat's-beard (T. pratensis), a biennial, growing in grassy pastures and meadows, on a loamy or clayey damp soil. The root is tapering, flowering in June; the whole herb very smooth, abounding with milky juice, rather bitter, but not acrid. Stems several, round, leafy, often purplish, 1½ to 2 feet high. Leaves long and taper pointed, often falcate, or curling at the extremity. Flowers large, 2 inches wide, bright yellow, opening very early in the morning, and closing before noon, except in very cloudy weather. The roots and young shoots have been eaten as pot-herbs.

2. The purple goat's-beard (T. porriformis), also biennial, grows in most meadows, near great rivers; herb smooth, 3 or 4 feet high, glaucous. The dull purple flowers, like the preceding species, close at midday; thence it is called in the country Go-to-bed-at-moon.—(Smith's Eng. Flora. vol. iii. p. 337.)

GOAT-WEED (Capraea bifrons). An uninteresting species of plants, of easy culture. The leaves of this genus are liked by goats; hence the common and generic names.

GOGGLES. See SHEEP, DISEASES OF.

GOLD and SILVER FISH. These beautiful creatures were first introduced into England from China about the close of the 17th
GOOSE.

The first are of an orange colour, with very shining scales, and finely variegated with black and dark brown. The silver fish are of the colour of silver tissue, with scarlet fins, with which colour they are curiously marked in several parts of the body. These fish are usually kept in ponds, basins, and small reservoirs of water, to which they are very great ornament. It is also a very common practice to keep them in large globular glass vessels, frequently changing the water, and feeding them with bread and gentles. The gold fish is now abundant in the river Schuylkill, near Philadelphia, into which they first made their way in consequence of the over-flowing of a fish-pond in Pratt’s garden, where considerable numbers were kept.

GOLDEN CLUB, called also Never-Wet, and Floating Arum (Orotonium aquatum). A plant not frequent in pools along the fresh water streams of the United States. It has a perennial root, leaves enlarging, finally to 8, 10, or 12 inches long, and 3 to 5 inches wide, a little succulent, very smooth, of a deep green and velvety appearance on the upper surface, paler and somewhat glaucous beneath. Flowers yellow.

GOLDEN OAT GRASS. See Avena.

GOLDEN-ROD (Solidago, from solidare, to unite, on account of the supposed vulnerary qualities of the plants). This is an extensive genus of coarse flowering plants suitable for the back of flower borders. Any common soil suits them, and they are readily increased by division of the roots. The common golden-rod, or wound-wort (S. virgaurea) is a native of Britain, growing in woods, hedges, heaths, and copses; and on mountains at every degree of elevation. It is perennial, and flowers from July to September. It is a very variable plant in magnitude, number, and size of flowers, and serrature of the leaves: nor do these varieties altogether depend on situation, except that in alpine specimens the flowers are larger and fewer. The root is woody, with long, stout, simple fibres; the stem usually from one to three feet high, never quite straight, purple below, most downy in the upper part, where it terminates in a leafy cluster, either simple or compound, of bright yellow flowers. When bruised, the whole herb smells like wild carrot. Its qualities are diuretic, astringent, and perhaps tonic; and it has been recommended as a vulnerary both externally and internally, but it is now never used in medicine. It may, with greater advantage, be employed as a dyeing drug; for, when the leaves and flowers impart a beautiful yellow colour, which, according to Bechstein, is even superior to that obtained from woad. The Canada golden-rod (S. Canadensis) is frequently used for this purpose. (Eng. Flora, vol. iii. p. 438.)

Solidago is exclusively a North American genus of plants, with the exception of 5 or 6 species in Europe, and 2 found near Canton, in China. About 50 species of golden-rod have been enumerated by botanists in the United States, some of which are, however, regarded as mere varieties. (Nuttall’s Genera.—Flor. Corn.)

GOLDEN-SAXIFRAGE (Chrysosplenium, from chrysos, gold, and splen, the spleen, in reference to the deep yellow colour of the flowers, and the supposed medicinal virtues of the plant). This is a curious and rather pretty genus. It requires a moist situation, and may be increased by dividing the roots. The native species in England are found in the greatest perfection upon the shady banks of small rivulets. There are several species both perennial and annual, flowering in May. The alternate-leaved golden-saxifrage (Ch. alternifolium) has the root fibrous and creeping; stems angular, decumbent, branched at the top only; leaves alternate, reniform, rough on both sides the notches, but the under disk pale and polished; radical leaves on long stalks, those of the summit crowded and sessile; flowers in a corymb, deep yellow. The opposite-leaved golden-saxifrage (Ch. oppositifolium) resembles the preceding, but is paler; the leaves smaller and the flowers of a pale lemon yellow. (See SAXIFRAGE.)

GOLD OF PLEASURE (Camelina sativa, wild flax). This is rather a dwarf plant, growing from 1 to 2 feet high, which is found in cultivated fields, chiefly among flax, with whose seeds it is often introduced from abroad; but it does not long propagate itself with us spontaneously. It is an annual, blowing small, pale-yellow flowers in June. It is cultivated in some parts of Europe for the sake of the oil, which is obtained from the seeds. The species of the genus to which it belongs have but little beauty, and require to be sown in the open border. See WILD FLAX.

GOOSE. A well-known large, web-footed bird, belonging to the order anatidæ, or swimmers. These are remarkable for their powers of swimming and diving; they are commonly called water-fowl, and, as an order, have frequently been designated palmpedes, in reference to their webbed feet. From the geographical position, extent, and varied character of the British islands, the species of this order are very numerous, comprising nearly one-third of the whole number of our British birds. The first family of this order, the anatideæ, is also extensive; including the geese, swans, ducks, and mergansers. The first three portions were formerly considered as belonging to but one genus, anas; and hence the family name, anatideæ. Modern systematic authors have found it more convenient, as well as desirable, to divide them into smaller groups, which are known to be distinct in their character and habits. Many of the species are of great interest and value. The present article will, however, be restricted to some account of tame geese.

Two varieties of the domestic goose are indigenous to Great Britain, the gray and white goose, and the pure white, which is of a larger size. The first is our most plentiful breed: the second are bad breeders, seldom producing more than three goslings at a brood, and that only every alternate year. There is, also, the Chinese breed, which is naturalized among us, valuable for their early breeding, and quick fattening. The Chinese goose lays about the end of November, if the weather is not severe, and produces her goslings in January. These goslings, if kept dry and warm, are fit for the
GOOSEBERRY.

Table in April and May. This goose is, however smaller, less delicate eating, and more noisy than the common gray goose. The common goose begins to lay towards Candlemas, and after laying from 9 to 11 eggs, she sits so closely on her nest that she hides her little down. If, however, she shows a wish to sit when she has only laid two or three eggs, she must be driven from the nest, or be shut up for a day or two. She will then take to lay again. One gander and five geese are the regular stock to begin with: they will produce 50 goslings in a season. Geese are grazing birds: they love a common, but horses do not like their company in a field, as they object to feed after them. The herb called goose-grass they are immediately fond of, and it is plentiful always under hedges during the gosling season. Water is important to geese, but they succeed in situations where there is no pond: a large, shallow pan filled with water, sufficiently capacious to admit of their washing in it, has often answered the purpose; but a pool is most desirable. The goose-hovel should be low, well thatched, and not facing into the farm-yard, otherwise pigs will get through the goose-aperture. It should have a door, also, for the poultry-woman to enter. The nests should be composed of straw, lined with hay, and the birds should be fed near their home, to allure them to it. If some of the goslings are hatched before the others, they should be removed from the mother, kept warm in flannel before the fire, and returned to her when the whole brood are hatched. Thin barley meal and water is excellent food for goslings, with chopped goose-grass; they soon learn to eat oats, and feed themselves. Mow down hemlock, if any grows near the poultry-yard: it is pernicious in its effects upon poultry. Patten geese in small parties, as they love society. They should be cooped a month, fed plentifully with sweet oats, and a pure water in a narrow wooden trough. An experiment has lately been tried of feeding geese with turnips, cut up very fine, and put into a trough with water. The effect was, that six geese, weighing only nine pounds each when shut up, actually weighed 20 pounds each, after about three weeks' feeding with this food alone. Half-grown or green geese are delicate eating in June and July; but they need not be cooped, they must only be well fed. Goose feathers are valuable, and their dung is employed as a manure by agriculturists.

GOOSEBERRY (Ribes grossularia). The gooseberry is indigenous to Great Britain, some other European countries of cool temperature, and also to the mountains of North America. The varieties of this fruit are too numerous to notice. By some botanists they are referred to two species, Ribes grossularia, the rough gooseberry, and R. uva-crispa, the smooth gooseberry; but others consider the latter as being merely a variety of the former, which is more correct, as it has been proved by successive reproductions that the rough will sometimes become smooth and the smooth rough. The gooseberry ripens in the extreme northern parts of Britain, if near the level of the sea; and at an altitude of about 900 feet, in the centre of the island, it acquires great perfection of flavour. In the southern counties, if the season be warm, it cannot bear full exposure to the vertical rays of the sun: in such cases evaporation takes place from the surface faster than the subjacent tissues can supply the loss, the superficial cells get emptied, and the fruit dies.

In England the gooseberry is esteemed one of their most valuable fruits. In spring it furnishes the earliest as well as the best fruit for tarts and sauces: and can be preserved green as well as ripe for winter use. When ripe it makes an excellent jam, a delicious sweetmeat, a luscious wine, and is a favourite dessert.

The following selection is recommended for small English gardens: Reds—Old rough red, Melling's crown bob, Farmer's roaring lion, Knight's Marquis of Stafford, Champagne and Capper's top Sawyer: one of the best of the red gooseberries is the Scotch ironmonger: it is hairy, and thin-skinned. Yellows—Hardcastle's gunner, Hills's golden gourd, Prophet's rockwood, Hamlet's kilton, Dixon's golden yellow, Gordon's viper. Greens—Edward's jolly tar, Massay's heart of oak, Nixon's green myrtle, early green hairy, Parkinson's laurel, Wainwright's ocean. Whites—Coleworth's white line, Moore's white bear, Crompton's Shebandeen, Saunders's Cheshire lass, Wellington's glory, Woodward's whitesmith. Smooth skins become tough in cooking, and should not be selected for that purpose.

The gooseberry can be raised from cuttings, from suckers, or from seeds: the former is generally resorted to as being the most expeditious; and seed is only sown to raise new varieties. Cuttings may be planted in the fall, or as early in the spring as the weather will permit.

The gooseberry is, comparatively, but little cultivated in the United States, though there is no doubt that in several districts of the Middle and Eastern States it could be brought to as great perfection as in England. It is a native of the soil: and loves to climb the sides of our mountain ridges, and if planted in places that somewhat resemble its native habitats, it would no doubt repay our care. It ought to have an airy situation, a rich soil, and a dry subsoil is essential, or it becomes infected with mildew. If it has no natural shade, during a few hours in the middle of the day, it must be shaded from the extreme heat of the sun. The berries acquire their finest flavour when brought to maturity gradually, under a low temperature. In pruning, instead of the lateral young shoots being cut close in, immediately above the first bud at their base, as recommended in colder climates, two buds should be left, to produce leaves to shade the fruit in summer. The vigorous-growing varieties ought to be preferred for planting.

GOOSEBERRY CATERPILLAR. For the destruction of these insects fumigations of various kinds; dusting with quick lime, and other methods have been resorted to, but they do not always answer the purpose. Wetting them by means of a proper syringe, with fresh lime-water, whilst the sun is shining strongly, is said to be a very effectual remedy. The
roots of the plant are not made wet by this operation which promotes the growth of the bushes and helps their bearing properties. Tobacco liquor is also often found a good application for the destruction of caterpillars, and also the solution of whale oil soap, as recommended for the destruction of aphides. The latter remedy is also said to be completely effectual in removing the mould, rust, or mildew to which the gooseberry-bush is so very subject, an affection which would seem to be capable of propagation with the plants. Mr. S. R. Gummere, of Burlington, New Jersey, an intelligent botanist, and successful horticulturist, states that the rust mould to which the gooseberry-bush is subject, may be prevented by carefully removing the buds from that portion of the cutting which, in planting, is inserted into the ground.

Seventeen or eighteen species of gooseberry, says Dr. Darlington, are enumerated as natives of the United States. Of these the Missouri currant (Ribes aureum) is much cultivated, and greatly admired for the beauty and spring fragrance of its flowers.

GOOSEFOOT (Chenopodium). An extensive genus of plants, of which 13 species are enumerated by Sir J. E. Smith, as natives of Britain, viz. 1. Mercury goosefoot (C. bonus Henricus), growing in waste ground and by roads sides frequent, and occasionally in pastures. The root is branchy and fibrous; the herb dark green, nearly smooth; stem a foot high, terminating in a compound crowded cluster, or spike, of numerous green flowers; their stalks sometimes uncouth and mealy. This, our only perennial chenopodium, may be eaten, when young, like spinach, and is cultivated for the table in some parts of Lincolnshire. It is insipid and mucilaginous, rather mawkish, and soon becomes tough and fibrous. Neither goats nor sheep relish this plant, which is also refused by cattle and hogs.

2. The upright goosefoot (C. urbicum), and 3., The red goosefoot, also occur commonly on waste ground; the former sometimes on dunghills, and the latter in low, muddy situations.

In exposed situations the whole herb of C. rubrum assumes a red colour. This species and its allies are said to be poisonous to swine; 4. The many spiked goosefoot (C. botryoides); 5. The nettle-leaved goosefoot, 6. The maple-leaved goosefoot, call for no observation. The whole plant of the two last species is felt; 7. White goosefoot, or common wild orache (C. album), is found in cultivated as well as waste ground everywhere. The herb is mealy, with a silvery unctuous pubescence, which, by age, becomes dry and chalky. The young plant is reported to be eatable when boiled, and is known by the name of fit-hen in some parts of Norfolk. It is eaten by cattle, sheep, and hogs, which last devour it with avidity; 8. The fig-leaved goosefoot (C. freifolium). Flourishes most on dunghills, especially about London; 9. The back-leaved goosefoot (C. glaucum), varies in height from 2 inches to 2 feet, and grows for the most part on a sandy soil; 10. Standing goosefoot (C. oldium). This species is found very commonly among sand or rubbish near the sea. The whole herb is of a dull grayish-green, covered with a greasy mealiness, which, when touched, exhales a strong, permanent, nauseous odour, like stale salt fish. It is, nevertheless, eaten by cattle, horses, goats, and sheep, but refused by swine; 11. The round-leaved, or all-seed goosefoot, or upright blite (C. polycarpicum, or C. centaurea) is also said to be eaten. In the best remedy is also said to be effectual in removing the mould, rust, or mildew; 12. The sharp-leaved goosefoot (C. acetosum), are two other species, which are less common. The former is a curious plant, whose numerous black shining seeds might perhaps be advantageously employed in fattening poultry; 13. The sea goosefoot, small glasswort, or sea blite (C. maritimum): this species abounds on the sea-shore, and grows also in sandy as well as muddy places, flowering in July and August. Stem thick and juicy, leaves smooth, about an inch long, salt to the taste, of a light bright green. Dr. Withering mentions this as an excellent pot-herb. In Siberia and Astracan the inhabitants obtain from this plant their potash, which probably takes more of the nature of soda. The alkaline salt contained in this herb renders it serviceable in making glass, though it is inferior to some kinds of sal soda found in the south of Europe.

Ten or twelve species of goosefoot have been found in America, six of which Dr. Darlington has detected in Pennsylvania. Most, if not all, are supposed to be foreigners. They are a homely family, generally regarded as weeds. Those best known are the C. album or lamb's quarter, used sometimes as spring greens; and the C. anthelminthicum, or wormseed, a plant having a strong, disagreeable odour, and yielding the well-known worm-seed oil, a valuable and powerful vermifuge.

GOOSE-GRASS (Galium trifidum). Three-cleft galium; also known by the common name of ladies bed-straw. This native American plant is met with in moist, low grounds and thickets, where its small, white flowers appear in July. Its root is perennial, the stem, rising 1, 2, or 3 feet long, and much branched. Professor Hooker thinks this may be distinct from the G. trifidum of Europe, which, he says, is a more slender plant than ours. (Flor. Ces-trica.) See HARRIET.

GOOSE-GRASS, DYER'S. See Madder, Wild.

GOSPY-GRASS. The generic name of cotton. This plant, which administers so greatly to the wants of man, and to the wealth of countries producing it abundantly, has been known and employed by the Asians and Egyptians in the fabrication of clothing, from the earliest dates of antiquity that have reached us. By the Greeks and Romans, however, it does not appear to have been in use. Pliny informs us that in Upper Egypt, on the borders of Arabia, grew a shrub called gossypion or zylon, the fruit-pod of which enclosed a sort of soft wool, of which the garments of the Egyptian priests were manufactured. Goe, which, in the Arabic, implies a silky substance, is doubtless the root of the word designating the genus of the plant. There are several species of the cotton plant, cultivated in different parts of the world, which may be resolved into the following: 1. The common Green-seed Cotton of the United States, the Gossypium herbaceum of botanists, — fig. 1. This has a smooth stem, leaves with five lobes, 2 z 2 645
which are round, mucronate, and serrate. It grows from two to five or six feet high, bearing yellow flowers on the end of its numerous branches, which flowers are succeeded by roundish capsules or bulbs, full of seed and cotton. 2. The Tree Cotton (G. arboreum) has a high perennial stalk, with branches six or eight feet long, five-lobed, palmate leaves, and yellow flowers, succeeded by oval pods. 3. Five-leafed Cotton (G. rutilatum), fig. 3, with lower leaves five-lobed and palmated, the upper leaves three-lobed. 4. Hairy Cotton (G. hirsutum), with the uppermost leaves undivided and heart-shaped, the lower three five-lobed, the stems and branches hairy, the flowers yellow, succeeded by oval pods. 5. Spotted-barked Cotton (G. religiosum), fig. 4, with the upper leaves three-lobed and lower five-lobed, and branches spotted with black. 6. Barbadoes Cotton (G. Barbadense), fig. 2, branching 4 or 5 feet high, with yellow flowers and oval pods, the upper leaves three-lobed and lower five-lobed, with smoothish stems.

The cotton blossom, though described as yellow, is very often only slightly so, and that while just blowing, appearing almost white when in full bloom. When withering, the blossoms appear reddish; and the whole process of efflorescence continues but two or three days, when they fall off.

In those portions of southern Europe where cotton is produced, Naples, Sicily, Malta, and especially the Levant, the Green-seed or common cotton is the only one cultivated for the wants of commerce. The hairy cotton is sometimes raised in the West Indies, although the Barbadoes is the species most commonly cultivated. In the East Indies and in China, the common and tree cotton are cultivated, together with some other species or varieties, especially that which produces the nankeen-coloured cotton. This cotton has been introduced into the United States, where it is now raised in sufficient quantity to manufacture the yellow cotton cloth called nankeen, which was, till lately, all imported from China.

The seeds of the common cotton are eaten in the Levant, where they are esteemed wholesome and nourishing. All the species afford a valuable oil from the seeds, which, besides being eaten, is used for burning, and many other purposes connected with the useful arts.

Niccolò Fabri, long known as the tobacco plant, and Sir Walter Raleigh has the credit of introducing the potato into Europe. Two monks, in the reign of Justinian, brought the eggs of the silk-worm from China to Europe, concealed in the hollow of a bamboo. But of the individual who first introduced the seeds of the cotton plant into America, history is silent.

He was, perhaps, one of that class of which examples are daily met with, who take pleasure in seeking out objects either curious or useful, and dispensing their acquisitions to others. The cotton is a pretty plant, bearing a beautiful flower, and was therefore, perhaps, first dedicated to the parterre of the American garden, where it appears to have long remained, devoted to ornament, and of little further use. Authentic information shows that in 1736, and probably earlier, it was an object of horticulture in Talbot county, on the eastern shore of Maryland; and although it may have been raised in squares and patches in neighbouring provinces, no particular attention was bestowed upon it as a profitable crop, till some time after the date mentioned. In 1744 a small quantity of cotton was exported to Europe from South Carolina, the warmer climate of which and the neighbouring provinces, was found more favourable to the crop than the peninsula between the Chesapeake and Delaware Bays, where its culture was first attempted. (Am. Farmer, vol. ii.) It was not, however, until the Revolution caused the supplies of foreign materials for clothing to be cut off, that necessity drove the American planters to raise cotton extensively for home use; and so general did this culture soon become, when urged by this necessity, that the cotton region was made to extend as high north as the lower counties of the state of Delaware. At the close of the Revolution, great financial distress prevailed throughout the States, which had achieved their freedom at the expense of immense pecuniary sacrifices. Many were the plans suggested by individuals and public bodies, called upon to consider the ways and means adapted to relieve the embarrassments of the times. The subject came up before the celebrated Convention of Annapolis, in 1786. The late President Madison, a member of that body from Virginia, who had given much attention to the subject of the cotton culture, here expressed it as his decided opinion, that, from the results of the garden culture in Talbot county, and numerous other similar proofs furnished in Virginia, there was no reason to doubt that the United States would one day become "a great cotton-producing..."
GOSSYPIUM.

The agitation of the subject was commenced in the public prints of Philadelphia, and the promising capacities of soil and climate, in essays and discourses read in and about the year 1787, before the societies which were led to the consideration of this and other matters calculated to advance the interests of the country. The most early and decided proof of the practicability of raising cotton crops to advantage in the United States, was first received in a letter from Mr. Leake of Georgia, addressed to General Thomas Proctor of Philadelphia. When it is estimated that the cotton brought to Philadelphia about the year 1787, and some time after, sold for the consumption at two shillings sterling, or four-ninths of a dollar, the increments to raise it may be readily imagined. Congress being at length convinced that the States could produce sufficient cotton for domestic use, in the first reformed tariff bill laid a duty of three cents per pound on that brought from other countries. American cotton began to be an important article of export in 1798 and 1799. It was, however, soon discovered that more could be raised than could be picked or cleared from seed by hand, the only mode of accomplishing the object then known, and the one which had been practised by the Egyptians and Eastern people for thousands of years. Eli Whitney, a native of Massachusetts who emigrated to the south, invented a mill to gin, pick, or separate cotton from the seed, and this with such facility as to perform in one day the labour of three thousand pair of hands. To work or attend this mill, impelled by water-power, requires only three persons. Thus, by the aid of machinery, the capacity to prepare cotton for market was made equal and even superior to the immense productive capacities of the climate and soil of the Southern States. These two facts, (says a writer in the American Farmer, vol. ii.) First, the capability of the southern country to produce cotton, and, Secondly, the invention of the water saw-gin, have effected the greatest and most enriching change in the agriculture of the United States, ever experienced by any people, ancient or modern. And to this view must be added the results of inventions, principally in England, but many in America, of those labour-saving machines and processes to pick, rove, spin, double, twist, wind, weave, dye, print, bleach, dress, &c., all within a comparatively few years.

Such are the considerations which are calculated to inspire correct views of the importance and extension of the cotton crop of the United States, the immense exportable produce of which has so much favoured every branch of domestic industry in other parts of the country; for those States situated too far northward to admit of the advantageous culture of cotton, by which the attention of the southern planter is almost exclusively engrossed, supply him with bread-stuffs, meat, horses, mules, and most other important appliances of life. The necessities of the Revolution, and subsequent financial embarrassments of the country, led to the development of the cotton culture in the United States; whilst the last war, by cutting off the customary supplies of British and other foreign fabrics, taught the Americans to manufacture for themselves, and thus opened to the producing States a home market for their exuberant cotton crops.

The progressive development of the cotton culture in the United States is shown in the following statement of the crops for different periods; viz.—

<table>
<thead>

It is estimated that good lands yield, on an average, from 250 to 300 lbs. of clean cotton per acre, and inferior lands from 125 to 150 lbs.; and that the capital invested in the cotton culture in the Union is about $500,000,000. The annual value of the crop is about $50,000,000, and of the exports $630,000,000.

The cotton exports of the year 1840 were as follows:

<table>
<thead>

We annex an account of the home consumption.

| Quantity consumed, and stock remaining in the hands of United States manufacturers, Sept. 20, 1841 | 297,288 bales |
| Do. Sept. 30, 1840 | 269,103 |
| Do. of 1839 | 275,015 |

The cotton produced and gathered in the United States is stated, in the returns accompanying the census taken in 1840, at 790,479,257 lbs., which product exceeds two-thirds of the annual cotton crop of the whole world, this being estimated at 1,000,000,000 lbs. Of the whole amount raised in the United States, South Carolina furnishes about 1-13th. Every year, however, opens new lands in the West to the
cotton culture, where congeniality of soil and climate to this commodity increases the product per acre, far beyond the average in the old cotton States. This consequently reduces the value far below those prices which formerly poured so much wealth into the Southern States. These newly cleared lands yield, on an average, 2500 lbs. of cotton per hand, whilst the lands in the Carolinas yield but 1200 lbs. per hand. As the expenses on a labourer are about the same in either place, this home competition must be almost ruinous to the old cotton States, to say nothing of that which is threatened abroad in India, South America, and Egypt. In a recent speech in Congress, Mr. Dixon H. Lewis declared that cotton, divested of government embarrassments, might be raised in Alabama for three cents a pound. (Southern Review for April, 1843.)

There were formerly three species of cotton commonly cultivated in the United States: 1. The Green Seed (G. herbaceum), popularly and commercially called Upland Cotton: 2. The Black Seed, producing a fine, soft, long, and strong cotton, of a good staple. This, from its flourishing in the lower country, and especially the islands on the coast of South Carolina and Georgia, has been called the Sea Island cotton. It is regarded as a variety of the Arboreum or Tree Cotton, and on new alluvial soils, in warm situations, is found to live 4 or 5 years, and attain a height of 18 feet, assuming the character of trees rather than shrubs. But when the cotton grows so large, it yields no adequate return to the cultivator. The seed of Sea Island cotton originally obtained from the Bahama Islands about the year 1785, being the kind known in the West Indies as the Anguilla cotton.

Of late years, in addition to the Nankin or yellow cotton, two species or varieties of upland cotton have been introduced, which, in some places, have almost superseded the common green seed kind; these are the Mexican and Petit-Gulf, both of which agree in most of their botanical characteristics with the Hirsute or hairy cotton, especially in the rough stem and petals. The Petit-Gulf kind is exceedingly productive, and differs from the Mexican chiefly in this characteristic, and in maturing earlier, a great desideratum with the planter, since it allows him a longer time to gather the crop. Some think the Petit-Gulf a mere variety of the Mexican, improved by its transportation to the banks of the Mississippi, where the soil and climate are peculiarly favourable to its development. The planters of the upland sections have to purchase their Petit-Gulf seed from the neighbourhood of Rodney, where it now costs only 25 cents per bushel. The 4th year after removal from this locality, it has so degenerated as to be no more productive than the common green-seed kind, or better in quality.

It has been remarked, that in most if not all the species or varieties of cotton cultivated in the United States, especially the herbaceous and hairy kinds, the close, short fur immediately enveloping the seed, somewhat analogous to the fur on an animal, has a tendency to increase in quantity. This, though it tends to render the separation of the long wool more difficult, has no other disadvantage.

The introduction of the plough, of the horsehoe, cultivator, and other contrivances for saving labour and improving the culture, have been of great service to the cotton as well as to the corn-planter. By the practice of drilling in rows set wide apart, the same fields may be cultivated frequently without such rapid exhaustion as would attend a different course.

The land is thus tilled sometimes three successive years with the drills being run at first 4 ½ feet apart, the position of the drill-rows being changed every year, so that the cotton does not occupy the same place two successive years. At the end of the 3d year the 3 drill-rows will be 13 feet distant from each other, and thus the growing crop is annually furnished with fresh soil.

The following account of the cotton culture, as conducted in the Southern States, is abridged from a highly interesting essay upon the subject by Mr. Thomas Spaulding, of Sapelo Island, Georgia:

"It was soon noticed by cotton growers," says Mr. Spaulding, "that soil and situation had more than common influence, as well upon the quality as upon the quantity of cotton produced upon any given portion of land. Certain soils and situations retained in the cotton its original appearance, an intenseness of yellow in its blossom, a fruit full and sound, a seed quite black, and free from fur or dow; while upon other soils and upon other situations the plant, the flower, and fruit was putting on other appearances. The plants, as if anxious to adjust themselves to a new temperature, took on a more coarse configuration of limbs and stem, a thicker branch, a rougher, larger, and more scalloped leaf, a more cone-like pod, a seed covered either in whole or at its points with the close down or fur that has already been described. At first the most careful cultivators were anxious by selection to keep the seed as much as possible resembling the seed first introduced; that is, black and free from down, and the more so as it was most easily separated from the cotton by the machines employed, and was considered most productive; but in process of time the varieties that stole up among the original stock was found to produce a finer and more uniform and longer wool. The current of selection has now, therefore, directed itself another way, and these hybrids, for I believe them to be so, although the germs of these changes may have lingered for ages in the original seed without developing themselves, have taken on three distinct appearances in seed; neither in blossom or plant differing to the eye from each other, although greatly differing from the parent stock, as being coarser and rougher in their form and leaf, with blossoms of a lighter yellow; having bolls larger and more cone-like in their shape. The finer cottons of the sea islands are obtained from these three varieties of seed; one with little or no down upon it, but with a long beak or point, to a seed longer than the original; a seed with down upon the two ends, but still with the pointed beak; and, thirdly, a long seed with a sharp
GOSSYPIUM.

beak, but completely covered with a soft, close, fine fur or down inseparably connected with the shell of the seed. These new varieties which produce the cotton now most in request, are later in perfecting their fruit, and have, consequently, increased the uncertainty of the most uncertain and doubtful crop to which perhaps human care was ever directed.

"There is a long string of islands extending from Georgetown, in South Carolina, to St. Mary's, in Georgia, that is, from 32° 30' to 30° north, a distance of about 200 miles. These islands were covered with live oak and other evergreens of a southern climate. They had been the abode of the red men of the West, but rather when the natives were fishermen than hunters; and the vast accumulation of oyster, and clam, and other shells, mingled with the remains of the bones and pottery of their old inhabitants, fill every stranger with astonishment, and the multitudes which their remains would bespeak, or the long time that must have been required to introduce such accumulated masses. These decaying shells seem to have intermingled with the original sandy soils of these islands, and digesting the vegetable matter that fell from trees and other sources, formed with them a light and fertile loam. These islands at an earlier period of colonial story, had been employed in growing indigo. It was upon two of these islands, surrounded by the salt waters of the sea, and separated from the continent by several miles of grassy, but salt meadows, that the cultivation of the sea island cotton commenced.

"If Frederick the Great never forgot him that introduced a better description of rye into Prussia, and if Swift is right in saying he merits a great name who will make two blades of grass grow where one had grown before, why should we deny to the dead what may be their due! The first cultivators of the sea island cotton in Georgia were Josiah Tattnall, and Nicholas Turnbull, on Skideway island, near Savannah; James Spaulding and Alexander Bisset, upon St. Simon's island, at the mouth of the Altamaha; and Richard Leake upon Jekyll island, adjacent to St. Simon's. For many years after the introduction of the Anguilla cotton, it was confined to the warm highland of these islands, bathed by the saline atmosphere, and surrounded by the salt water of the sea. Gradually, however, the cotton culture was extended into lower grounds, and beyond the limits of the islands, along the eastern shores of the continent, into soils containing a mixture of clay, and lastly into coarse clays deposited by the great rivers where they met the tides of the sea. In all these soils the cotton plant grows well. In all these soils fine cottons are produced. The only essential property that is required is a saline atmosphere; with it any soil in Georgia or Carolina may produce fine cotton; without it no soil will produce fine cotton.

"It is within this district of country, from Georgetown, in South Carolina, to St. Mary's, in Georgia, and extending not more than 15 miles from the sea, to which the sea island cotton is still confined. Whenever it has been carried either south, or north, or west beyond these limits, a certain decline in quality has followed its removal. Many changes have taken place in the manner of cultivating the sea island cotton since the first introduction. When first introduced, the seed was deposited either in hills raised a little above the common surface, at 100 feet or more distant each way, or in holes at the same distance apart, and the intermediate spaces were dug up, pulverized, and kept free of grass or weeds by the hand hoe or by ploughing. But it was soon found that this distant planting, with a few seeds only, left a great portion of the field unoccupied by plants, and, consequently, unproductive; for, as it has already been said, the cotton plant is one of the tenderest productions of vegetable life. The growers of cotton found it, therefore, necessary to increase the quantity of seed, to insure a sufficient number of plants, and to bring them nearer together. Fortunately for the cotton culture, Tull's book upon husbandry had been more read in the Southern Colonies than in England; and his ridge husbandry was adopted for sea island cotton, and is particularly adapted to it, I may say necessary to its successful culture.

"The present process (and it has been the same for 25 years past) is to make up the field into ridges occupying 5 feet of space each, and extending in straight lines across the entire field. If the land is at all low, or subject in any degree to water, these ridges are intersected at 105 feet from each other by ditches which receive the water that may collect in the hollow spaces upon which the cotton plant is growing. These hollow spaces represent the water furrow in wheat cultivation, and serve the same purpose, that is, in directing the redundant water that falls, into the drains that take it off the fields.

"A field is well prepared to receive the cotton seed when drains intersect it at regular distances when the surface of the land is thrown up into ridges of 5 feet, rising about 10 inches above the intervals, the crown of the ridge flat, broad, and regular. A trench is then made along the middle of the ridge from 2 to 4 inches, dependent upon the time of planting, which extends from the 1st of March to the 1st of May. Upon this subject, as upon all others in which men are concerned, wisdom is found between the extremes, and experienced growers of cotton generally prefer planting from the 1st to the 15th of April. When cotton is planted early in March, before the sun has warmed the soil to a certain depth, it is necessary to deposit the seed in drills not more than two inches deep, or there will not be warmth enough to vegetate the seed. Later in the season, when the power of the sun has increased, it is necessary, in seeking for that moisture which is as requisite for vegetation as heat itself, to sink deeper into the soil, and the drills which are then made to receive the cotton seed are required to be 4 inches deep. From the many accidents to which this feebly plant is subject in its first growth, experience has taught the sea island cultivators, that it is necessary to place many more seeds in the ground than can grow there; and it is usual, therefore, to sow at least 1 bushel of cotton seed to
the English acre. The persons employed in planting the cotton are generally divided into gangs of three. One of these opens the drill along the top of the ridge; the most intelli- 
gent of them carefully drops the seed into the 
trench, while the third follows in his, or more 
often in her steps, and a hand-hoe returns the soil 
while yet moist into the trench from whence it was taken. For myself, I pre-
fer performing this operation with the foot; it 
is less troublesome to the labourer than carry-
ning and using the hoe. It keeps the mind in-
tent upon one operation rather than two. 
Walking along erect, the feet are alternately 
employed to return the soil into the trench 
upon the cotton seed; and the whole weight 
of the person brought to bear upon the foot that 
has just performed the operation, presses the 
yielding and crumbling soil into close contact 
with the seed. This pressure of the foot after 
sowing, is like the roller in English husbandry, 
and is as beneficial to cotton as the roller is 
known to be to wheat or other grain. But 
after all this care you are never sure that 
from your first sowing a sufficient number of 
plants will stand. One night's frost, which 
sometimes comes as late as April, will destroy 
the whole field, and drive you back upon your 
labours; one day of a strong, dry, northeast 
wind will tear, blight, and destroy your whole 
field; and upon the best and richest soils, 
when both these evils are passed over, there 
is another ensuing, equally destructive. The 
cock-chaffer or cut-worm is to be apprehended 
during all the month of April, and as the cot-
ton comes through the ground, and remains for 
several days, like the pea or other pulse, with 
but two radical leaves, every one of the plants 
that are cut by the worm, either above or 
below the ground, are destroyed; so that it is not 
frequent that whole fields have to be re-
planted in the month of May, about which 
time the worms pass immediately away. 
At the close of the month of May, when appre-
hension from these accidents have passed 
away, a new labor begins. The numerous 
plants which crowd the ground begin to injure 
each other, and must be removed. Prudent 
persons divide their removal into three opera-
tions, gradually adjusting the number to the 
increased growth of the plants, which are at 
length left in the drills, at from 6 inches to 24 
inaches apart from each other, depending upon 
the fertility of the soil and the expected growth 
of the plant, which rises in altitude, from 3 feet 
to 8 feet; and it is well to ob-
serv, that the cotton plant is a leguminous 
plant (a green plant), a plant that sends its 
roots down into the ground, and draws much 
of its nourishment, by its broad leaves, from 
the atmosphere. This increased distance in 
the drill, therefore, is rather to allow space for 
the plant to extend itself at its inclination, 
than from a desire to add nourishment to its 
roots, for at last the whole field should be 
shaded from the sun when the plants are fully 
grown, and the number should be adapted to 
that end.

"But at every one of these thinnings, as they 
are called, or drawing of the plants, the field is 
cleared with the hand-hoe from all weeds and 
grass, and new soil brought up around the re-
maining plants to support them, now binding 
to every wind, from their tall but feebly struc-
ture. This course of thinning, when it is ne-
necessary, and the weeding, and grassing, and 
drawing up, which is always necessary, con-
tinues until about the 20th of July. By this time 
the operation has been repeated from 3 to 
6 several times, dependent upon the soil and 
season. About the 20th of July we may ex-
pect our summer rains should commence. 
These rains are not tropical, but they approach 
to tropical in their violence. Up to that time 
no climate can be more temperate than the 
climate of the sea-coasts of Georgia and Caro-
olina. Volney, from report, supposed it the best 
in the United States, and the writer of this paper 
believes it is so. The atmosphere is elastic, 
the winds that blow every day from the sea are 
cool and refreshing; they bring health and 
healing upon their wings; they drive the 
vapours which have been gathered upon the wa-
ters, or that have arisen from the marshes 
which margin the shores, over the woods of 
the interior. But the time has now come 
when evil spirits should prevail. These va-
pours have been collecting dark and ponderous 
clouds upon our western hills; the equilibrium 
of our atmosphere is destroyed. Whether it 
is that the adjacent seas have become heated 
by the mass of warm water which the gulf 
stream brings along the coast, or that the 
same general cause which operates with such 
great power within the tropics, operates in part 
here, I know not; but from the 20th of July to 
the 1st of August, the winds change from 
southeast to southwest, and bring clouds 
charged with lightning and rain, in such 
masses as to deluge our fields. From the time 
this change takes place all labour in the cotton 
field should cease; for the plants with broad, 
succulent leaves, and tall and slender stem, 
the heavy and natural in its growth, and for its 
structure, can illly bear up against beating 
rains and strong winds, and requires all the 
support that the original ridge in which it was 
planted, and the repeated dressings up which 
have been directed, can give it. And hence 
arises the necessity of the ridge husbandry of 
the sea island cotton in Georgia and Carolina, 
and the importance of the repeated gathering 
or dressing up of the soil to the plants, which 
has been described. The month of August is a 
month of doubt and anxiety with the cotton 
grower. Too much rain makes the plant cast 
off its fruit, its blossoms, and even its leaves. 
The full moon in the month of August, too, is 
the time when the caterpillar is expected. This 
worm proceeds from a small brown butterfly, 
greatly resembling the candle moth. This 
moth or butterfly deposits its eggs upon the 
leaf of the cotton plant always a night or two 
before the full or change of the moon. They 
hatch in a few hours after they are deposited, 
then so small as scarcely to be visible to the 
 naked eye. Like the silk worm, they appear to 
linger in their first stages, doing no great in-
jury during their first 9 or 10 days. But a few 
days before they have completed their growth, 
they become voracious in the extreme, and like 
the visitations of the locusts in the East, destroy
whole fields in a few days. We have seen 400 acres of cotton that looked promising and well to-day, and that 4 days afterwards had not a green leaf, and scarcely a small pod remaining upon it. These destructive visitations, judging from the past, may be expected once in about 7 years. When cotton fields have escaped injury from rains, from wind, or worms, they offer as beautiful a spectacle to the observer as the cultivation of any plant can present. One wide and waving field of green leaves, covered for the longest time of July to the 1st day of September with blossoms of 3 colours, and with a multitude of pods of every growth. The blossom, on the first day of its coming out, is of a fine, yellow colour, and it sustains that colour during the day. It changes under the influence of the night air to a crimson or red hue; and again, on the third day, it becomes of a rich chocolate brown, and falling to the ground leaves a pod already of half an inch in diameter. The time which intervenes from the blooming to the opening of the fruit, greatly varies, depending upon the season. We have marked hundreds of blossoms which ripened and perfected their cotton in 21 days from the day of blossoming; and again we have frequently seen them require six weeks to arrive at the same end, which is, however, a bad omen as to ultimate results.

"The cotton pods begin to open about the 1st of August. From this time to the 1st of December the whole attention of the cultivator is directed to the picking in of the cotton as the pods daily open. During this autumnal season in Georgia and Carolina, upon the seacoast, the winds are violent and the rains heavy; so that the operation is tedious, although not laborious; and during this time the persons employed may be expected to gather from the field 25 pounds per day, when the weather admits of gathering or picking cotton as it is called. When every thing is favourable, the persons employed should bring in 50 pounds daily of cotton in the seed; but as the gathering is continued in the day as they bring in 10 pounds, 25 pounds may be considered the full average of labour so directed. There are few subjects upon which there is more contrariety of opinion than upon the real amount of product given by the soil in any cultivation; agriculturist as I am, loving my profession as I do, seeking information to enlighten my labours as I have done, I know no book upon which I can lay my hand which would give me correctly the real mean result of labour or of land employed upon any one object through out a whole extended district. The Abbe Raynal kindly tells us how many coffee plants and how many cotton plants grew upon the French part of the island of St. Domingo; and yet there was not one planter in St. Domingo who could really have told how many cotton plants or how many coffee plants grew upon any one arpent of his own field. Taking, however, the best means my long experience would give, I should say that a labourer cultivates, in sea island cotton, 4 English acres, and that these 4 acres yield, as the result of his labour, 280 bushels of clean cotton, or cotton separated from the seed, which consists of 400 weight of white cotton and 100 weight of coloured or stained cotton; and that these 500 pounds of clean cotton have, for the last 15 years, averaged to the grower 20 cents per pound for his white cotton, and 10 cents per pound for his stained cotton, yielding in American money, consequently, $90 to the labourer—a small remuneration, certainly, to the cultivator, and not calculated to excite jealousy or hostility in any other persons engaged in any other pursuit."

"Preparing sea island cotton for market.—"

The process of preparing the cotton for market commences as soon as it is generally gathered in from the field, and is tedious and troublesome in a high degree. The cotton, when gathered from the plant, is put into a bag, containing about half a bushel, which hangs upon the person engaged in the operation, suspended from the neck or waist as they may prefer, and when it is desired by them they deposit the contents of the bag in a large light basket, which contains the amount of cotton to be weighed in a certain time. At the approach of night, the cotton gathered in the day is brought home and weighed and deposited in a common house, from whence the next morning, if the weather is good, it is carried out and spread upon drying floors made of 2-inch American pine. These floors are of course proportioned to the quantity of cotton expected to be placed upon them at any one time, but may be estimated at 20 by 40 feet of floor to every 100 acres of cotton cultivated, and in that ratio of quantities upon these floors. If it has been gathered from the fields in good weather, the cotton is allowed to remain but one day to take off the dew of the morning or the damp of the night air; but if gathered in wet weather, it may require two or even three days' exposure upon the drying floors, which are raised upon posts three feet from the ground, as well to preserve the wood of which they are made, as to admit a more free circulation of air. It is, however, known that strong, cold winds or very bright suns, if continued too long; have an injurious effect upon the fibre of the cotton; and this extreme exposure to either wind or rain is, therefore, carefully avoided, and the cotton left no longer upon the drying floors than is necessary to preserve it from heating in the house. Before it is put up finally in the house, it is usual, and quite proper to pass it through what is called a 'Whipper,' to shake off any sand or broken leaves, or any other extraneous matter that may have attached itself to the cotton either in the field or in the gathering. The cotton having been gathered, dried upon the floors, and whipped, is ready for the next operation, or ginning.

"The whipper, which is a very necessary instrument in the well-preparing of cotton, is made of wood, is a long barrel composed of slats or reeds (or it would be better made of wire) 6 or 8 feet in length, and 2 feet in diameter, with one end closed and the other open, and is supported at the two ends by feet of different lengths, so that the barrel, in its horizontal position, declines about 1 foot at the lower end; a hopper containing about a barrel rests upon the upper side of the barrel, at the upper enclosed end of it. This hopper lets the
cotton that is to be cleaned fall into the barrel, through which runs in its whole length a shaft, which is turned by the hand by a crank attached to the shaft at one end. This shaft is intersected by rods which reach to within an inch of the barrel. The cotton, as it falls from the hopper, is whirled round by these rods until it escapes at the lower end of the barrel, by which time any sand or dirt, or leaves, or other matter attached to the cotton, has escaped through the spaces intentionally left between the slats or reeds, which constitute the external rim of this barrel or whirper. This whipping was formerly performed as well upon the cotton in the seed, as after it was separated from the seed; but the second operation of the whirper has lately been discontinued under a belief that it produced a stringy appearance in the cotton wool.

The whipping of cotton at its first gathering, and while attached to the seed, is really beneficial, and should never be omitted. When these leaves are within the rim of the house barrel, they may be considered as closed, and the preparation of the cotton for market really begins. Many machines have been designed, and many forms of the same machine adopted, for separating the seed from the sea island cotton, but all of them at last resolve themselves into two wooden rollers turning by opposite movements upon each other. The rollers are from half an inch to an inch in diameter, and revolve from 100 times to 500 times in a minute. The whole revolving itself into this simple rule, that the smaller the rollers, and the slower they revolve, the cleaner will be the cotton separated from the seed, because, if the rollers are an inch in diameter, and, above all, if they revolve with a high velocity, they will take in soft seeds, small seeds, and false seeds, or motes as they are called, and in crushing them in their passage through the rollers, will stain and injure the cotton in its appearance.

Much money has been spent upon costly machines, propelled by horses, by water, or by wind, first in the Bahama islands, and for many years in Carthage, but at last most of the growers of sea island cotton have returned to their first and most simple machine, to wit, two wooden rollers, kept together by a wooden frame and a square shaft, upon which is fixed a wooden or iron fly wheel from 2 to 3 feet in diameter. The iron cranks which turn the rollers are connected by strips of wood, with a treacle worked by the foot; this treacle runs under the machine, and is connected at the farther end of the floor of the house by sockets, within which it revolves; the man stands, therefore, in the front of the rollers, with a board between him and the rollers, upon which he holds a large handful of seed of cotton, which he presents from time to time to the rollers that are kept in motion by the pressure of the foot upon the treadle; this labour, from habit, becomes easy, as the feet are often changed in the operation. The task expected from the labourer with the machine (which costs, when new and complete, 10 American dollars) is between 30 and 900 pounds per day. Women, from their careful attention in keeping the rollers, while they revolve upon each other, well supplied with seed cotton, were unquestionably the best gimmers, as they are called from the term gin, applied to the machine; but in process of time it began to be believed that the continued motion of the feet produced a relaxed system in women, which was likely to lead to the end in abortion or miscarriage: men have, consequently, been substituted for this work, one which being within doors, and exercising both hands and feet without very much labour, is preferred by them to any other in the winter. This is a little surprising, this simple machine, the foot gin, which we received from the West Indies, is mentioned, if I mistake not, in the remains of 'Nearchus's' voyage down the Indus in Alexander's expedition, as gleaned and translated by Dr. Vincent or Major Rennell, in his map of Hindostan, as there employed for separating the seed from the wool, which the Greeks, for the first time, saw growing upon trees and shrubs. Could Asia Minor, could Greece and Egypt have been as far to the west, or nearer to that time! The inquiry is a little curious, nor is it uninteresting, but can better far be made by one who lives surrounded by much of the wreck of past knowledge, by many of the memorials of past time, than by him who is living in solitude, under the shadow of his oaks, on the shores of the Altamaha. To prepare the cotton for this ginning, or separation from the seed, when taken from the house where it was put from the field, it is carefully looked over and separated, or sorted, as it is called, the yellow cotton, the white, any hard cotton, that may have passed through the whirper, is separated from the white; this is a work of care and attention, and the future appearance of the cotton much depends upon the manner in which the work is done. Women are employed in this operation, seated upon benches with tables before them; the seed cotton is spread in small parcels, taken out of one basket, examined and turned over to another, into which the person puts the entire of her day's labour. The quantity required to be thus examined and cleaned in the day by each one is from 60 to 100 pounds, according to the care bestowed upon the cotton by the grower; after this sorting it is exposed lightly and shortly to the sun, that it may take off any dampness the cotton may have acquired in the house; it is then passed from this drying immediately to the gin, or machine that separates the seed from the wool; after going through the gin, and being separated from the seed, it is again turned over to the woman, who are generally in a large room, well lighted with glass windows. They sit with small tables before them, made either with open slats, reeds, or wire, when any crushed seeds, and cotton burnt or blackened by the former machine, or motes that have escaped the former searches, are removed; and to have this work well done, 30 pounds is all that is required per day from each woman. After this third operation it is considered ready to be bagged for market.

The bags in which sea island cotton is shipped contain, in this country, exclusively Scotch, are made of hemp, 42 inches wide in the web, and should weigh 1½ pounds to the yard; these
Two men are generally employed at a time in packing, and usually pack two bags in a day, in the manner following. The room into which the cotton has finally passed, after being prepared for the bag, is reserved expressly for that purpose, and is kept as clean in floor and walls as possible; adjoining to it is a small apartment under the same cover, with a round hole made in the floor just large enough to contain the bag when full of cotton; the open end of the empty bag is strongly sewed with twine, round a strong hoop, which, extending beyond the hole, suspends the bag vertically from it; one of the men then gets into the bag, and with a heavy wooden or iron pestle he presses the cotton gradually with his feet, and finally beats it down with the pestle until the requisite quantity is pressed down into the bag. The bags were formerly made wet before they began to fill them, under the belief that it kept the cotton down in the bag, when pressed there, better than when dry, but this is an idle and often an injurious practice, and should be always avoided. We will now look back and collect the quantities of labour that is or should be applied to every bale of 300 pounds of sea island cotton in preparing it for market. It requires 1000 pounds of seed cotton to produce 300 pounds of clean white cotton wool; 15 persons will be required to sort and prepare this 1000 pounds for the gin or machine; taking all weather 25 pounds is the mean quantity received from each gin per day; this gives 12 days' labour to each bag for ginning, and 10 women mow these 300 pounds of cotton in the day, making for sorting 15, for ginning 12, for mooting 10, for packing 1, in all 38. But besides these 38 that must be good and steady persons, there are usually two inferior persons, young or old, to place the cotton which is about to be ginned, under the gin floor, to move and pass about in any change of weather, thus requiring to every bag of sea island cotton well put up the labour of 40 persons 1 day. The bag costs for bagging, for twine, and trouble in making, not less than $1.25 of American money; this, with 75 cents for freight, is to be subtracted from the value of cotton, as there is never any return made for the bag by the purchaser.

"The quantity of sea island cotton has not materially increased within these last 10 years, nor is it likely that it will increase. The particular soils and climate that have heretofore produced it, and to which it probably owes its quality, are confined to the limits first stated, that is, from Georgetown, in South Carolina, to St. Mary's, in Georgia. By looking at a map of the United States, it will be seen that the long string of islands that bound our southern shore, and separate the Atlantic Ocean from the continent, end at these points; but what is more, the tides that probably assisted to cast up these islands, have changed their climate. The tides along the shores of North Carolina and Virginia, are much less than in Georgia, and they rise still less in Florida and the Gulf of Mexico, that bounds the new acquired provinces of the American Union to the southwest.

"Whether it is that the cultivation of the sea island cotton has afforded fewer inducements than other subjects of cultivation, certain it is that the number of those engaged in it, even within these limited districts, have not greatly increased, and it is the successors of the first cultivators that are still engaged upon this object. They are generally an educated people, and a stationary one, less anxious after change than their countrymen are supposed to be; and although severely smitten in war by England, and, in peace, by the National Tariff, they have still clung, with some degree of fondness, to the places whereat they were born, and to the seas in which they were bred.

"Short Staple Cotton.—The short staple cottons, of every part of the United States, are derived from the first and second varieties of cotton which were found in the United States, from Virginia to Georgia, at the close of the American revolutionary war, cultivated in small quantities by the poorer classes of the white population of the country, to be mixed, in their domestic manufactories, with their own wool. The cotton for this purpose was separated from the seed by the old and the young with their fingers, sitting around their evening fire, and was spun by the hand wheel, to serve as a warp, to be filled with the wool of their own sheep.

"As soon as the attention of the Southern States was called to the profitable cultivation of cotton, by a few persons along the shores of Georgia and Carolina, the cultivation began to be extended into the interior. The small quantity of cotton that had been grown for domestic uses, was exchanged for larger quantities, to be prepared for sale. But the great difficulty to be overcome in the progress to extension, was to find out any instrument by which the cotton wool could be separated from the seed.

"By this time various machines had been introduced for ginning the sea island cotton, but all of them ended at last in two rollers revolving upon each other, either longer or shorter, and moving with, some more, some less, velocity. Those rollers were but badly adapted to the hairy cotton, or second variety, which soon began to obtain the preference in the interior of Georgia and South Carolina, over the first or smooth-leaved variety, and which is preferred to one that prefers a warp when separated from its downy seed, a finer and stronger, although shorter fibre, and as perfecting its fruit sooner, but which it was almost impossible to separate with the rollers, because the down or fur upon the seed retained the seed hanging upon the roller, and denied admission to the rollers of the fresh cotton in the seed that was offered. Many plans were suggested, many substitutes for the rollers designed. All succeeded in part, but still they went on slow. Something was desired to do much in a short time, something that was strong enough to travel about without being broken to pieces, and light enough to move with its moving master. At last such a thing
GOSSYPIUM.

was found in Miller and Whitney's gin, probably not the best machine that could have been designed, but so operative to its end, so efficient in its purpose, that it took possession of the whole ground. From thence forward no other machine was sought for, and Miller and Whitney's gin is employed to separate the cotton seed from Virginia to Louisiana, save where the roller gin is used, and its use is now altogether confined to the sea island cotton, whose superior value is supposed to warrant the great increase of labour necessary in that mode of ginning. Miller and Whitney's gin was designed by Mr. Whitney, and executed at the plantation of Mr. Miller, 16 miles above Savannah, about the year 1796, and it seems to be derived from two machines already used upon cotton, a kind of cylindrical whirper, and the circular cards, before that time introduced in manufacturing cotton, a wooden shaft or roller enclosed within a wooden box. This roller or shaft has at every inch of its length a steel blade or saw about a foot in diameter; above these saws is a box containing the cotton in the seed. The box has the bottom of metal slits, through which the saws pass about an inch, and pulling off the cotton, but sometimes, and a cotton roller it passes. This revolving of the saws carries the cotton in the box gradually round, until the seeds contained in the box are freed of the wool attached to them, when it is emptied of the seed and re-filled with fresh cotton; it too often leaves some of the fibre behind it, which diminishes the quantity as well as injures the quality, so much so that the estimated difference of the products in these two modes of ginning are, with rollers, 300 pounds to the 1000, and 250 pounds to the 1000 with Miller and Whitney's gin. This gin having at last given a cheap and expedient mode of taking the wool from the hairy American cotton (for a gin that cost 10 pounds sterling will clean a bale a day with a single horse acting upon the gin, with a band wheel which any man can make for himself), the cultivation of this description of cotton diverged in all directions around Georgia as the common centre; it went north into the two Carolinas; it went west into the hill country of all the Southern States; it was found capable of adjusting itself to the soil and climate of the interior country, which the Anguilla cotton had not been adapted to; still the fibre of the hairy or short staple cotton is better near the sea than in the interior. Above all, it is found to be most productive in alluvial soils that are a little touched with salt, as are some of the districts of Louisiana, where the rivers rising in the Rocky Mountains draw some of their waters through the salt and arid plains which separate the waters of the Arkansas from the waters of Red River, where these two varieties of cotton and a cotton that is possibly hybrid between them, have arrived at the greatest perfection. It was there that soils which are freely tinged with red, and heavily seasoned with salt, which all the tributary streams of Red River, flowing in from the north, bring with them, give forth the most abundant crops of the best quality of these descriptions of cotton. Directing myself by the information received from one or two friends who have property there, I should say, with reasonable diligence and attention to the object, 1000 pounds of seed cotton, or about 250 pounds of cotton wool may be expected to the English acre, while the average products of the hill lands, from the Mississippi to North Carolina, should not be taken at more than 500 pounds of seed cotton, or half the quantity; nor do I believe there is any material difference upon the great scale of products through this wide extent of country, judging for myself from personal observation, for I have passed through all these districts, yet scarcely a year passes without the newspapers announcing some new-discovered land of promise within these wide limits, themselves misled by some single or partial result, or stimulated on by land speculators, a curse of no common character to a new country. But in whatever cause originating, the evil is the same. These rumours fall among a people already heated with a desire of change—a people quite sensible to present evils, but not reflective enough to hold in remembrance that every wave of the hand without necessity, and every momentary evolvement of time without usefulness, is a waste of power and waste of time irrevocably assignable to humanity. The system of agriculture through all those districts is essentially the same. You find the Virginian upon Red River; you find the North Carolina man, the South Carolina man, and the man from Georgia, alongside of him; any improvements, any increased quantity of product, by any new course of cultivation, spreads like the fire of the American prairie, a spark has carried it, and enkindled it, far in advance of the mass of flame that rolls after it. Any substantial improvement, therefore, that is made in Virginia or Georgia, from this extension of mind, from this intermingling of men, is as likely to be reflected back upon the intermediate country from Red River as to reach it from its first source. The system of cultivation is, therefore, the same; the moment the cultivation of cotton spread into the interior country, from the shores of Georgia and South Carolina, the hand-hoe was exchanged for the plough. The latter instrument had been employed at all times and in all cultures in the hill country of the Southern States; in no agricultural country were oxen or horses cheaper, in no agricultural country were soils freer for the ploughshare, but it was not adapted to the sea-coast, because the land is so little above the waters that ebb and flow, that many drains, inconvenient to the ploughman, are required to carry off the surface waters. The trees, too, of necessity, send their roots along the surface, rather than vertically in quest of moisture, and many of them, like the live oak, are scarcely destructible by plough. Thus to North-duct his course; but, above all, the plant under cultivation sends its roots around in quest rather of nourishment than down in quest of moisture, and must not be too readily dealt with. These various causes have, finally, after long experience, fixed the hoe husbandry upon the sea-coast, and carried the plough husbandry into the hills. The short staple cotton is, therefore,
as exclusively cultivated by the plough, as the sea island cotton is exclusively cultivated by the hoe. The manner of treating the plant is really the same; the hoe dressing the land more neatly and garden-like, the plough breaking up the land more radically, and extending far more widely its operation for the quantity of force employed. The consequence has been, that while 4 English acres is the quantity cultivated upon the sea-coast of Georgia and Carolina with the hand-hoe, 8 acres is about the quantity cultivated of short staple cotton, in the interior, with the plough. It is the ridge husbandry in both instances that is now pursued; more neatly executed, in the first instance, by the hoe, and more roughly by the plough in the second, but still the same. The month of April is the best time of planting either variety. The distance between the ridges is most generally 5 feet, the plants left in the drills varying from 6 to 24 inches, dependent, as before stated, upon the expected growth of the plants. Two or three instances contributed to aid the cultivation of short staple, extrinsic of soil or real products. The winds of autumn are far more violent upon the sea-coast of Georgia and Carolina, than in the interior country, and the capsules that contain the sea island cotton expand more than those that contain the short staple, so that the first has to be gathered much more frequently from the fields than the last, or it falls to the ground and is lost. The consequence is, the general gathering to the labourer per day is more that are on streams of the staple than of sea island, for it is allowed to hang upon the plants until they are white with the open cotton, so that there is only 2, and at best 3, gatherings of the one, to 10 or 12 scanty gleanings of the other. This one circumstance, more than any other, gives to the grower of short staple cotton the power of something more than duplicating the quantity of cotton wool produced by the same quantity of labour expended.

Cottons of various kinds grow well, and perfect their fruit, from the southern borders of Virginia to the southwestern borders of Mississippi, a space of 1200 miles, and from the sea for 200 miles into the interior; through this wide space of country, in every soil, whether of clay, or loam, or even sand, the cotton plant will grow, and produce its seed and wool, its accompaniment, provided the waters are kept well drained from the surface of the land. The quantity of products will of course depend upon the soils, whatever they may be, containing these ingredients, which constitute fertility in all countries, which neither experiment or the philosophy of chemistry has yet been able fully to discover or define. The mean quantity given of 100 pounds of sea island cotton wool to the English acre, and of 125 pounds of short staple cotton to the same quantity of land, we believe not materially wrong, but the quantity of labour to bring forth these results are very different. The sea island cotton is cultivated nearly by the hoe, the short staple more roughly by the plough; still it is, or should be, the ridge husbandry in both instances. The plants are left to stand in drills upon the ridge, at distances from each other, graduated as before stated, to the expected growth of the plants from 6 inches to 2 feet from each other, and bearing, without injury, to stand much nearer than at first sight may be imagined, for the cotton plant does not occupy much space with its roots, sending them down into the ground, and not over the surface, like white or grain crops, and drawing like all large-leaved green crops, much of its nourishment from the atmosphere. It is not an exhauster of soil, shading and protecting it from the sun, and soon, by its decay or by its combustion, returning almost as much as it has taken away; but from the density of its shade, and the size and swell of its roots, it soon makes the soil too loose to sustain the plant, and the continued culture of the same soil, brings on a disease in the plant greatly resembling the blight in wheat, and leaving a propensity in the seeds of cotton to extend the evil, like the propensity in blighted wheat to grow, but not extend. I am inclined to believe that in both instances the evil had originated in insect depredations, for although Sir Joseph Banks discovered a fungous attaching itself to blighted wheat, I still believe that the microscope discovered in that minute parasitic plant the effects of injury previously received from something that lived and moved and had animal being. Fire, therefore, I have always believed, and have always acted upon that belief, is the best security against this increasing and extending evil; all the weeds and grass that are on streams of the staple than of sea island, for it is allowed to hang upon the plants until they are white with the open cotton, so that there is only 2, and at best 3, gatherings of the one, to 10 or 12 scanty gleanings of the other. This one circumstance, more than any other, gives to the grower of short staple cotton the power of something more than duplicating the quantity of cotton wool produced by the same quantity of labour expended.

There is no plant that requires the interchangeable husbandry more than the cotton plant, and there is no country where that husbandry is more essential than in the Southern States. The cotton requires continued cleaning during the droughts of spring and the heats of midsummer; these cleanings, together with the shade and rapid growth of the plant, break up the soil, and leave it to be carried away by the first violent autumnal rains. The best remedy is to give to the fields of cotton intermediate crops of grain; as good a series as can well be adopted is cotton, rye, and wheat (where the soil is fit for it), pasture, and again cotton. A more extended rotation might be adopted, but as all root crops should be avoided in series with cotton, this simple tri-annual course, with manure applied during the grain year, to as great extent as may be convenient, will keep the field without material decay. When cotton was first introduced, the growers were misled as to the necessity of this change, by observing that the cotton plant, upon new lands, grew large, and gave little fruit, and that it improved for the second and third year in productiveness, they unfortunately pushed the culture too far, until possibly to this cause many of the diseases that have afflicted it in its growth may be attributed.
GOSSYPIUM.

In a preceding part of this article, the probable mean results for these last 15 years, in growing sea island cotton, has been taken at $90, or about 200 sterling to the labourer; and taking, as we have already done in this letter, the medium crop of short staple at 125 pounds to the English acre, and 8 acres of this cotton, as cultivated by the plough, it will give 1000 pounds of short staple cotton wool to each labourer employed upon it, which for the last 7 years may have given to the grower a mean return of 10 cents to the pound, or 100 dollars for the year’s work. There are exceptions, unquestionably, to these estimates; a few men have received much higher prices for their sea island cotton, and a few men have raised much larger quantities of both descriptions of cotton to the acre than are given, but exceptions can never serve as a guide, in conclusions, as to either the wealth or productiveness of a whole country.”

Mr. Croom, of Middle Florida, thinks Mr. Spaulding has made the limits within which the crop of sea island cotton may be cultivated too narrow. He states that “it has been raised in Middle Florida since its first settlement about the year 1822; and the crops made here have been annually sold in the Charleston market, at prices a little exceeding, generally, those of the ‘Mains and Sanjeees,’ though not quite equaling good sea islands.” Moreover, it is produced from the coast to the distance of 30 miles inland, but, at the same time, it is not denied that the presence of sea air is beneficial to this crop. If I have not been misinformed, this cotton is also produced by the planters on the St. John’s, in East Florida, and was formerly produced in the Bahamas, until the ravages of the caterpillar compelled its abandonment. I think it may be doubted whether Mr. Spaulding is correct in the opinion that this cotton becomes less fine when carried southward of the equator. It is probably a native of a tropical climate, and, therefore, might probably be not as fine when produced in the West Indies. I have heard that some of this cotton produced at Cape Sable has commanded 50 cents per pound in the Charleston market, without unusual care in its growth and preparation.

“In limiting the range of the short staple cotton to 200 miles of the sea-coast, Mr. Spaulding appears to have overlooked North Alabama and West Tennessee. In receding from the sea-coast, however, two causes are constantly operating against the growth of cotton; a higher latitude and a greater elevation, both tending to produce a colder climate. To these causes may probably be added a third, the loss of sea air. Other things being equal, the cotton planter, therefore, should prefer the neighbourhood of the sea-coast.”

To Mr. Spaulding’s highly interesting account of the cotton culture we shall add some further details of a miscellaneous character. The quantity of seed cotton usually from 1 to 2 bushels per acre. This is scattered in the rows drawn upon the cotton beds, and very lightly covered. It sprouts and comes up in a very few days. If injured from too early planting, it seldom recovers from the effects, and matures late. When worms or lice attack the young plants, it is advisable to stop thinning the plants, and replant as quickly as possible. The crop is a precarious one. In favourable seasons more cotton is sometimes raised than can be picked, whilst in others there is such a falling off in the product as to leave many hands unemployed, or but partially so. Much wet weather occurring in the spring may lead to serious injury of the young plants, and in the latter part of the season the same kind of weather may cause the bows to shed or fall off too soon, and thus spoil the cotton. The kind called Petit-Gulf, now so highly prized by planters in Mississippi and some other states, is not only of finer quality, but more productive and easily gathered, a hand picking 20 lbs. per day more than of the ordinary upland kind. But it sheds its bowls much sooner, and does not admit of picking more than half the usual time of the common green seed species, which last is often gathered during 4 months of the year. Hence the planters in some places put in only a part of the crop of Petit-Gulf, reserving another portion of the common kind for later gathering.

The distance between the rows is usually regulated by the strength of the soil and capacity for producing vigorous plants. It has been recommended as a good rule to place the rows on land capable of producing from 10 to 15 bushels of Indian corn per acre, about 4 feet apart; from 15 to 25 bushels per acre, 5 feet; from 30 to 50 bushels, 6 feet; 50 to 70 bushels, 7 and 8 feet. It is important to be in readiness to plant as quickly as possible after frosts have ceased, one week in the first part of the season being considered worth a fortnight in the latter part. As soon as the fourth leaf makes its appearance, the thinning by hand commences, when the plants, if to be cultivated in drills, are allowed to stand two and two, from 9 inches apart in light land, to 2½ and even 3 feet where the ground is heavy. When the crop is dry, it may be ploughed, and the dirt drawn up to the cotton so as to cover and smother the young grass. When wet, the grass and earth are drawn away from the cotton very gently, after which the ground is ploughed and drawn up again as soon as sufficiently dry to permit. This plan of ploughing and hoeing is followed up until the cotton becomes so large as to be injured by the passage of the plough, after which the earth is chopped over with the hoe until the crop is made, of which a judgment may be formed by its beginning to open freely at the bottom. Ten hands are considered enough to cultivate 100 acres of cotton with ease; but if a good crop, it would require at least 20 hands to pick it out.

The advantages derived from substituting the plough to the hoe, so generally used in the low lands of the old cotton states, are strikingly exhibited in the following communication from a Georgia planter to the editor of the Farmer’s Register. We shall only give extracts from this article, which may be found in the 6th vol. p. 269.

“An emigrant from your own state, and the vicinity of your city, formerly engaged in the culture of the long-staple cotton on the main
GOSSYPIUM.

lands, conversant with the modes of culture prevalent there, and now engaged in growing the short cotton upon the plans adopted throughout the whole western country, my experience has enabled me to detect some of the errors formerly practised by myself, and my neighbours in Carolina. My attention has been called to this subject by the perusal of an article in one of your late numbers, signed 'An Observer,' giving an account of the crop of E. Frost, Esq., in St. Andrew's parish. Mr. Frost, it appears, planted, according to the low-country system, four acres of cotton to the hand, and each hand made 4,000 pounds seed cotton. This the writer considers an extraordinary production—and, for that region of country, so it is. It may safely be predicted that it will not soon be equalled by Mr. Frost, or any of his neighbours. With hands till lately accustomed to the same manner of working, I planted last year 10 acres of cotton and 10 of corn to the hand. I never had a cleaner crop, and though the season was excessively wet, my negroes never performed their tasks with greater ease. The cotton crop, seriously injured by the worm, yielded 800 lbs. to the acre, and 8,000 lbs. to the hand. Mr. Frost's land exceeded mine in productiveness, yet my crop doubled his. His is considered so extraordinary, that it is held up as an argument against emigration—mine was an ordinary crop, nearly doubled by many of my neighbours. But the question to be solved is, how is the difference in the results obtained?

"It is unquestionably true that the soil and climate of the west is better adapted to the growth of cotton—that here a plant of the same size, and on a soil of equal strength, will send forth and retain a greater number of pods, than upon the sea-board. It is equally true that the grass will grow as rapidly and as plentifully in the one place as in the other. The difference in the soil and climate has not, however, as much influence as is generally imagined by residents on the sea-board. Would they adopt the same management, pursue the same modes of culture, which, somewhat modified, they unquestionably can, there can be no doubt that, though they could not obtain the success of the western planter, yet they would make some approximation toward it."

With regard to the management by which so large a product was obtained, the judicious use of the plough was considered as the chief agent. By it the beds were prepared for planting, the trenches or drills made, and the seed covered. By it the most part of the grass was destroyed, and the plant furnished with the earth requisite for its support and sustenance. By it the use of the hoe was in a great measure superseded. "It may," says the writer, "interest some of your readers who groan under the pressure of their crops of 8, 10, and 20 acres, and cotton to the hand, and whose fears are alarmed lest the grass should overrun them, to learn how, by the use of the plough, 20 acres to the hand can be planted, and the same crop secured. I will, therefore, give you in detail the arrangement of the crop on our plantation last year. There were, besides the regular crop, 75 acres of oats, potatoes, and slips, enough for the use of the plantation, and about 15 acres of wheat. The plantation worked 30 hands—15 at the plough, the rest with the hoe. In March, 300 acres were planted with corn, on land previously well ploughed and checked. In the first week of April, 300 acres of cotton were planted. The land was prepared by throwing together with a turning-plough, in the alleys of old cotton-fields, four furrows. Thus bedded, the drills were opened with a small scutter, or bull-tongue plough, in which the seed was sown; they were covered by a board fastened on the plough-stock, in the place of the mould. The drilling, planting, and covering occupied four days and a half. There was an excellent stand, and no replanting necessary. The ploughs and hoes then went into the corn-field. These were well ploughed and hoed by the time the cotton was out of the ground and required work. The cotton was four times ploughed, and as often hoed, and when laid by in July, a hat would have held all the grass that could have been found. The crop was twice more ploughed, and once hoed. The grass was constantly kept down by the ploughs. The daily task of a hoer was 100 rows of cotton 100 yards long. The first and second hoeings, when the cotton had to be chopped out and reduced to a stand, proved good, though not severe tasks; the other hoeings were light, and the workers were often out of the field by 12 o'clock. The crop was well worked, and with ease, by low-country hands, who would think it the worst calamity that could befall them to be compelled to return to the place of their nativity. The males and horses were in as good, if not better, condition than when the ploughing commenced."

Picking.—The bowls of cotton mature and open about the last of August and beginning of September, when the picking commences. This is performed by hands, male and female, who are provided with osnaburg bags hung over the neck and shoulders, into which the cotton is placed as fast as picked. These, when filled, are emptied into large osnaburg sheets, placed in convenient spots. These sheets are carried home in the afternoon. The pickers are cautioned to guard as much as possible against a small leaf, which, when dry, often intermixes with the cotton, and never can be got rid of, thus injuring the sale. The general average in what is called a good opening is from 45 to 50 lbs. per day to each hand. The freshly picked cotton is first dried upon scaffolds made about 4 feet wide, so as to admit of reaching far enough to turn it over with ease whilst drying. A cotton-house is at hand to receive the cotton in case of rain. After being perfectly dried, the short-staple or upland cotton is ginned and prepared for market.

There are several kinds of guns used for cleaning the seed from its abundant seeds, such as the Barrel gin, Eves's gin, and Whitney's gin. The last is that depended upon for ginning the green seed, upland, or short-staple cotton; the long-staple or sea island has still to be prepared for market by hand, involving tedious and expensive operations. Whitney's saw gin, for separating the seed from upland or short-staple cotton, is a mill worked by oxen or
Gossypium.

water. "The teeth in the circular iron plates serrated, about three-fourths of an inch apart, fixed to a cylinder, draw the cotton wool from the seeds through the iron stamp out of the bin and hopper in which the cotton is placed. These openings are too narrow to suffer the seed to pass. The cotton is brushed off the saws by counter-moving brushes on another cylinder. By an ox gin, 6 to 900 lbs. are cleansed in a day. After ginning, the cotton is picked of all remaining broken seeds and trash, and packed in bags of 250 to 300 lbs."

Varieties of Cotton.—Besides the Mexican and Petit-Gulf, some other kinds have recently obtained great celebrity in the United States. One is called by some the twin, by others the Alridge cotton, the first name being derived from the peculiar manner in which the branches shoot out from the stalk, the second from its supposed first introducer. There seems to be some doubt as to the origin of this cotton. The advantages claimed for it are, 1st, its being better able to stand the effects of drought; 2d, not casting the squares however severe this may be; 3d, admitting of very close planting in consequence of the great shortness of its branches; 4th, the rapidity of growth and production, a merit which has never been observed in common kinds. The advantages of maturing early, and thus allowing a longer time for picking, is, as before observed, a great desideratum to the planter. The superior merits of this new variety of cotton caused great competition for its seed, which at one time sold for $5 per quart, and even 50 cents the single seed.

A communication in the 7th volume of the Farmer's Register (p. 252), makes the following statement in relation to this variety, which, from a resemblance in its stalk to a member of the Hibiscus family, has been called Okra cotton.

"A Mr. Terry, of Autauga county, Alabama, some years ago bought some Petit-Gulf seed. A single stalk was observed in a field without limbs, and having great numbers of bolls adhering immediately to the stalk, or in clusters on very short limbs. The cotton had all been picked out except a single lock with nine seeds. From these seeds this variety has been propagated. The seed sold, in 1837, at 50 cents a piece. Last fall I bought at $160 a bushel. The cotton examined by me exhibited a distinct variety. It had rarely any limbs longer than one joint, sometimes two; the bolls were two, three, and as much as seven in a cluster. I had one limb about 4 inches long, with 7 good bolls opened on it. The stems of all the bolls shooting from one place, at the top of the short limb. The cotton was exceedingly fine, being, I think, 2 to 4 cents a pound better; being in colour and staple the finest and softest short-staple I have ever seen. It opens earlier. The field I examined was planted the 20th of April. At a very intelligent party, living in the neighbourhood, told me he planted similar land on the 1st of April, and that the new cotton was open two weeks earlier than his. It grows in good land quite tall, say 6 or 8 feet; and in this, I fear, will be the greatest objection to it, as it may fall when heavily fruited towards the top; but perhaps this may be avoided by top

Gossypium.

ping. Its advantage to an Alabama planter, if it succeeds in rich prairie lands, will be its early opening, by which the worm will be avoided; the tremendous drought, which has eaten up full one-third of my crops for five years. The appearance of the stalk is more like okra than any other—the leaf being a cotton leaf."

Another writer in the same periodical, speaking of the two new kinds of cotton, says, "There are two distinct varieties of twin or okra cotton. The one called okra was discovered in Alabama, in first year's Petit-Gulf seed. It grows up generally in one tall stalk, sometimes as high as 8 or 9 feet, with very short limbs, which are seldom more than 6 or 8 inches long, and having its bolls in clusters of 2 to 7 or more. I have seen 10 blossoms or forms in one bunch. Sometimes 1, 2, or 3 long limbs put out near the ground, turn upwards, and grow parallel to the main stem, bearing fruit as it does."

"The other new variety of cotton is said to have been discovered in Chester District. It is now somewhat like the Alabama okra, without being the same. It is about a half-way plant between the okra and Petit-Gulf. It has never seen it taller than 4 or 5 feet. Its limbs are longer than the okra, and not as long as those of the Petit-Gulf. Both kinds have twin bolls, but the bolls and blossoms are more numerous in the okra. Two bolls on the same stem are frequent in both; but it is only on the okra that I have seen 3 blossoms within the same calyx, or 4, 5, or more bolls in one cluster. There is also a clearly defined difference in the Chester twin, a darker, green, and more naked seed. No person who has once seen the two plants growing, or the two kinds of seed, will ever mistake the one for the other."

"I am not prepared to say that the Chester kind is not a good cotton. I know too little of it. The staple is good; I have seen some stalks in gardens very well filled with bolls.

"To the Alabama okra there is one objection, which I think can be easily obviated. It grows too tall, and is liable to fall down. The remedy is to top it at 4½ or 4 feet. The stalk grows stronger, the bolls fill up larger, and the product is increased by it. As it will bear great crowding on the land, the yield will be greater than from Petit-Gulf. It is, in fact, an improved Petit-Gulf seed."

"Okra cotton is also called by some Alvarado cotton. With regard to its productiveness some idea may be gained from the following advertisement in the Columbia papers, offering for sale the seed of this cotton."

"Dr. J. H. Taylor, from little more than 3 of the stand he ought to have had, gathered upwards of 1,200 lbs. per acre. The following is an extract of a letter from Dr. Taylor: 'You may believe I had not more than of a stand, and planted, too, at 5 feet instead of 3, and yet I will make about 1,500 lbs. per acre. I believe it capable, on the same land, of yielding 5,000 lbs. planted at 5 feet in double rows. If I live another year, I will try 100 acres in that way.'" Mr. F. M. Gilmer, of Montgomery, Alabama, from as bad a stand, gathered 1,400 lbs. to the acre. Mr. C. T. Billingslea, of Bibb county,
GOSSYPIUM.

Alabama, from 1/4 of an acre gathered 1,060 lbs., and expected 200 lbs. more. Mr. Aldridge, who first cultivated this cotton, it is said raised 3,000 lbs. per acre this year, and realized $30,000 for his crop of 30 acres. Dr. J. H. Taylor, from 22,000 lbs. of seed cotton, ginned 13 bales of 600 lbs. average, or 35 lbs. of clean to 100 lbs. of seed cotton. Jesse P. Taylor, well known here, weighed 425 lbs. of Petit-Gulf and the same of okra in the seed, and ginned each; the result was 124 lbs. of ginned Petit-Gulf, or 29 lbs. to the 100, and of okra 156 lbs., or 36 lbs. to each 100 lbs. of seed cotton. The staple is decidedly finer.

The price of the seed here offered for sale is $100 per bushel, $20 per gallon, and $5 per quart; which are stated to be the Alabama prices.

Defects in Cotton as prepared for the Manufacturer.—The cotton manufacturers in England having met with certain defects in the sea-island or long-staple cotton, which they thought might be remedied by proper attention in the primary manipulation, have recently addressed a communication on the subject to Messrs. Browns and Welsman, extensive cotton importers in Liverpool, to be forwarded by them to the planters in the United States. From this we extract portions which indicate the defects complained of, as well as the qualities most desired by the manufacturer, to all which it may be the interest of the producers to give attention, especially since the competition which has sprung up in other parts of the world. The Manchester manufacturers say, we have often, in conversation with them, expressed our regret that the growers of fine sea-islands, in so many instances, injured their cotton by stringing and matting it in the getting up; and in hope of drawing their attention to the subject through the medium of your house, we beg to trouble you with the following observations.

"Fine cotton yarn is esteemed in proportion as the thread is uniform in substance, free from lumps, and strong. The latter has been decidedly improved by the introduction of the select seed cotton; but the leverness of the thread has been impaired rather than otherwise, and this arises from the multitude of small white specks, or nitters, with which the staple of the finer and softer kinds of sea-islands, and the select cotton seed particularly abounds.

"In examining these nitters through a microscope, we find them in general composed of kinds of fibres, presenting an appearance much resembling the misletoe plant in this country, and for some time we feared they were excrescences peculiar to the fine fibre, and inseparable from it; but the two recent samples of beautifully fine select seed cotton, sent us by you, are so free from this defect, that we have now a strong impression they are chiefly produced by an over-handling in the getting up; at least we can multiply such nitters here, by mismanagement in the cleaning process; and we have no doubt the same effect is produced in America. We would, therefore, strongly urge the planter's attention to this point; for in all cotton goods, such as gauze, muslin, and laces, it takes immensely from their value and beauty, and limits the use of the finer yarns, which are chiefly used for these articles. As an instance of this, we may state, that one of our customers informs us he frequently pays from 9d. to Is. per yard, upon his finest muslins, for picking out the nitters one by one with a needle, after the goods are woven—an expense which is equal to from 10s. to 30s. upon each pound weight of muslin. Our experience has proved that the softer and more silky the staple, the more easily it is nitered; and, as the spinners possess no means by which nitters can be removed from the cotton when once formed, the only means of remedying the evil is to prevent their formation.

"To this point, therefore, the attention of the grower should be strongly directed. All unnecessary handling, whipping, tossing, or shaking of the cotton ought to be avoided. It should be as well cleaned as possible, but yet free from stringiness, and the fibres left in the loose and disentangled state they must be before being separated from the seed. If this were attended to, it would materially improve the appearance of fine yarn, and remove the never-ceasing complaints of the fine muslin manufacturers, and, as we are persuaded, tend to increase the consumption of fine cotton goods."

The committee to whom this letter was referred reported:—"That the matter to which their notice had been directed is one of deep importance to the grower of that valuable staple production. If, in consequence of his neglect of an art of skill, the pound of muslin, which would otherwise command its full price, is depreciated from 10 to 30 shillings, duty and interest obviously impel him to the providing of a remedy at once prompt and efficient.

"Through the politeness of Messrs. Browns and Welsman, three samples of cotton, being specimens forwarded from Manchester, were received from Messrs. Gourdin, Matthiessen & Co. These samples are endorsed as follows:—No. 1, illy got up and nittered; No. 2, illy got up and partially opened; No. 3, well got up, in examining the bale, they report in No. 1, through a microscope that magnified one thousand times, they were discovered to be, in general, of a globular form, and to consist of filaments of cotton, with interstices of various diameters, readily reducible in size by pulling the long threads attached to the mass. This, however, could not always be done, as the knot of fibres constituting the nitter was in many instances too strongly formed. The committee next proceeded to the examination of samples of seed cotton. In about a pound, personally gathered by one of them, from fully matured pods, produced from healthy plants, no nitters were observed. In the same quantity picked from diseased stalks, which bore defective fruit, several were seen. These were subjected to the test of the microscope, and precisely the appearance that characterized those taken from the ginned cotton in No. 1 was exhibited. Repeated inspections since have produced no marked variation in the general results. The committee, therefore, with confidence deduce the inference, that preparation, except perhaps..."
in the isolated instance hereafter to be noticed, is not the cause of the nitter. In confirmation of the opinion, putting aside the conclusive facts adduced, the different processes through which the cotton passes, whilst in the hands of the planter, are only too numerous. After the stained is separated from the white, the latter is thrown, in small parcels, into a whirler, in order to extract the dirt and to throw off the short and weak fibres, which, if allowed to remain, would detract very materially from the value of the crop. This machine, constructed of wood, with round wooden teeth, is turned by the hand. Unless the door of the whirler be closed, which is never done, the egress of the cotton is quickly effected. After this operation the cotton is ginned, and then taken to the motting-house, where, on a frame of wood-work, it is gently shaken and partially opened by the hand. When clean, it is received by the packer, who, with a wooden instrument, compresses it into a bag, weighing, when finished, from 300 to 400 lbs. In these various but necessary modes of treatment, in not one of which any violence is used, the committee feel persuaded that the staple sustains no injury whatever. It is well known that every description of cotton, except the finest quality, and that of a sort, before it is converted into fabrics, is subjected to numerous operations, all of which are performed by machinery. From the willow, which, by its revolving spiles, tears open the matted masses, succeeded by the scutching machine, in which the cotton is beaten by metallic blades, revolving on an axis at the speed of from 4000 to 7000 revolutions in a minute, other machines with iron fingers, teeth, and wheels, follow, so that it may almost be said that, without the aid of human hands, the vegetable wool is opened, cleaned, spread, carded, drawn, roved, spun, wound, warped, dressed, and woven.

"Now, although it is represented that the superior qualities of black-seed cotton are not thus wrongly treated, yet, as they are 'opened and cleaned by being placed upon cords stretched on a wooden frame, and then beaten by women with smooth switches,' the committee are at no loss to perceive how the complaints of the manufacturers by their own act may be increased. This last mode of cleansing the raw material was very generally pursued by the planter a few years ago. Were he now to resume that ready method of preparing his crop for market, he is satisfied that, whilst his time and labour would be saved, the fabrication of fine goods would be likely to incur an additional expense of no ordinary magnitude. By using switches, it is nearly certain that the weak fibres are broken into minute parts, and, with the naturally short and rotten, intermix and become entangled. Although, therefore, the imperfection of the staple, which is the special subject of this report, is undeniably common to the cotton plant under peculiar circumstances, the committee think that the injury to the staple from that imperfection can be created by artificial means, and, from experiments instituted by them, is engendered by the different processes through which the cotton goes in its conversion into cloth, as already particularly described. That the nitter, however, is occasionally formed through the want of foresight on the part of the planter, when his crop, from adverse seasons or other causes, is defective in texture, is highly probable. The filaments of cotton are transparent, cylindrical tubes. When ripe, even before the bursts, the tubes collapse in the middle, forming semi-tubes on each side, which give to the fibre, says Mr. Baines, in his able treatise on the cotton manufacture of Great Britain, when viewed in certain lights, the appearance of a flat riband, with a hem or border at each edge. "The twisted and cork-screw form of the filament of cotton distinguishes it from all other vegetable fibres, and is characteristic of the fully ripe and mature pod. This form and character the fibres retain ever after, and, in that respect, undergo no change through the operations of spinning, weaving, bleaching, printing, and dyeing, nor in all the subsequent domestic operations of washing, &c. &c., till the stuff is worn to rags, and then even the violent process of reducing those rags to pulp for the purpose of making paper effects no change in the structure of these fibres. From the difference between the elementary fibres of cotton and flax, the latter being transparent tubes, cylindrical, and articulated or jointed like a cane, it has been incontestably proved that the mummy cloth of Egypt was linen.

"Unripe cotton is finer than that which has attained its full age, but is deficient in the other essential attributes of a perfect staple, strength and length. Some of the filaments, indeed, are not the eighth of an inch long, and until several days after the opening of the capsule are found doubled or curled, full of watery and oelaginous particles; the cotton is wet to the touch, and is of a brown hue. In this state, unless dried in the sun, it becomes more or less mouldy; the superfuous oil from the seed, which ought to have escaped, is diffused through the mass; the colour soon changes; heat is generated; and the staple, originally strong, is quickly perceived to be materially affected. Hence it is not surprising that in immature cotton, distinguished, as it is known to be, for its delicacy of texture, variability in length, and want of pliability, when subjected to the mildest mode of treatment to free it from extraneous matter, the threads should cross and mix with each other, thus forming artificial nitters. Within a few years, the action of the sun, with a view to the dessication of the wool, has been sedulously avoided by perhaps a majority of our planters. The daily gatherings are spread in houses, or under scaffold erected for the purpose, and thus the drying process, if a few exposures in that way is worthy of this appellation, is conducted. That the practice is radically wrong, for the reasons already assigned, the committee firmly believe. Damp cotton, also, can neither be ginned nor cleaned but with difficulty; this itself it is a sufficient reason why it must be added the indubitablc fact that, from its too ununctuous properties, the floating dust of the atmosphere tends to its discoloration.

"From these observations it will appear that nitters are either natural or artificial, and that
both are primarily to be traced to a defective staple, arising from diseased plants; that the artificial nitter may be generated even by the common method of preparation, unless the cotton is properly dried; and that the means to which the manufacturer is obliged to resort are evidently calculated to bring about the same results.

"Of these samples, Nos. 1 and 2, which are "illy got up," are lumpy and stringy, of a deep yellow tinge, and weak and uneven in fibre. The cottons from which these are taken, it is likely, were never dried; it is still more probable that they were the produce of a scanty harvest. No. 3 is of natural colour, open, and in texture strong and long. It is necessary here to remark, that the stringy appearance of cotton is not always, or even mainly, the fault of the planter. It arises principally from the same cause to which the nitter is referable: the imperfectness of the staple, or the immaturity of the fruit. This was especially true the last year.

"To two considerations, pertinent to the matter under review, it may be proper to advert. In every field, no matter under what sinister circumstances the crop has grown, there are small sections in which the plants come to perfection and bear healthy fruit. From these the cotton that is picked is marked perhaps by every characteristic of the best staple, yet, almost from necessity, it is thrown into the general bulk. Again, in harvest season the labourer cannot stop to examine, if he had the ability to know, the variant qualities of the cotton he is engaged in gathering, but promiscuously the bad, the fair, and the good are blended. This is unavoidable. Subsequently the stained is separated from the white, but the weak and strong continue together; a part only of the most deficient of the former being afterwards detached by the whipper.

"On the immediate topic of inquiry, the committee ask leave to conclude with the following suggestions:

"1. The necessity of drying cotton in the sun for 3 or 4 hours, as its dampness may seem to indicate.

"2. Select seed for planting, not with a view to superiority of staple, but the production of sound cotton. For that purpose, choose from healthy stalks those pods that are fully blown.

"3. The first pickings should be set apart, and not mixed with the general crop. The fibre is weak and short. The same course ought to be pursued with cottons gathered after a storm or much rain.

"4. Cotton ought to be thoroughly cleansed before it is carried to the gin. If it be well done the after-labour will be trifling, and the fault of over-handling avoided. Too much pressure on the roller gives to the cotton a matted appearance; if the pressure is unequal, it will be stringy.

"Before closing this report, the committee would offer a few reflections. Not irrelevant, they trust, to the occasion. For many years the sea island crop has scarcely repaid the toil and perseverance incurred in its production. From highly unpropitious seasons, the ravages of worms, and the cultivation of a plant peculiarly delicate and unfruitful, it may in verity be said that it is annually a subject of congratulation with the planter if his necessary expenditure does not exceed his profits. Except 1826, when the exportation was about 6,000,000 lbs., from 1833 to 1835 inclusive the production was less by from 1 to 7,000,000 than at any former period since 1821.

"The table from which the above (to 1833) is taken, was published in 1833, by Messrs. George Holt & Co., of Liverpool. It exhibits the extreme prices of cotton and wool in that place from 1806 to 1835 inclusive. The statement of prices from 1834 to 1836 inclusive, is extracted from a Liverpool circular, published in January last. The difference between the extreme prices has been assumed as the medium price. What the average price really was cannot with certainty be stated.

"The long staple is generally used for the twist or warp, and the short staple for the weft. In this way, the black seed is made to participate in the changes which, no matter from what cause, mark the market value of the green seed. This, perhaps, is the strongest reason why a more decided inequality in price between the fine and superfine qualities of long staple cotton ought to exist, to which may be added the variety of uses to which the former, alone or mixed, is applicable. From these considerations it is apparent that, in relation to those two descriptions of vegetable wool, the one is really worth from two to three-fold more than the other, instead of from 30 to 50 per cent, which continues to be paid.

"One pound of cotton usually makes 8 yards of coarse muslin, and is then increased in value from the raw cotton eight-fold. But, if spun in
the finest yarn, it is worth 5 guineas, and in 1780, if woven into muslin and tamboured, was worth 15l. It may now be converted into a piece of lace worth 100 guineas.—Report of the Secretary of the Treasury, 1836.

"The finest quality of sea island cotton, re-
marks Mr. Baines, in ordinary states of the market, is worth three times as much as the common quality of the same class. The va-
rieties in quality in most of the other denomi-
nations is from 20 to 25 per cent., and in none of them is more than 50 per cent.

The following Table, taken from the Liverpool Price Current, under date of December 9, 1842, is sub-
joined, as showing the comparative prices of cotton from different countries, and the sections of the globe where the staple is cultivated.

Diseases and Accidents to which Cotton is sub-
ject.—The cotton crop is not only rendered very uncertain from the effects of the weather, but frequently suffers the most serious injury from the depredations of insects. The most fatal enemy of the cotton crop in Georgia, Alabama, Mississippi, Louisiana, and Texas, is a disease called the red-brown, which has been thus described by Mr. Troup, in the 1st volume of the American Farmer. "The first indication is seen in a small circular spot on the outside of the bowl, exhibiting a darker green than the circumjacent parts, as if a globule of water had dropped upon it and been absorbed. Many of these are frequently seen at the same time on the same bowl. They spread themselves sometimes faster, sometimes slower, as if influenced either by the state of the atmosphere, or condition of the plant; changing colour as they progress until they assume a dark brown approaching to black, and until the whole exterior is affected in like manner, or until it receives from some cause a sudden check, and then this appearance is only partial. In the first case, the disease has penetrated to the centre of the fruit, the fermentation is complete and universal, and is seen in a frothy white liquid, thrown out on the surface. Putrefaction follows, and the destruction of the seed and im-
mature wool being finished, nothing is left but the rind or exterior coating of the bowl, which, exhausted of its juices, hardens and turns black, and thus terminates the process. In the other case (that of suddenly checked disease), the interior of the bowl, in some instances, remains unharmed; in others, is only partially in-
jured, and in this last case, the pods remaining unhurt, mature and expand. This, however, rarely happens, as the disease is wonderfully capricious, going and coming unaccountably; attacking at one time with more, at another with less violence: so that the fruit which escapes entire destruction on the first attack, may fall a victim to the second. Nor is this capriciousness justly attributable to changes in the atmosphere; its origin even does not seem to have any connection with weather. The year 1817, when rot first appeared, was one of remarkable wet. The year 1818, one of remarkable drought. The rot in 1819 was both more general and more destructive than that of 1817. In 1819, which has been as the planters say, a seasonable year, there is more rot discoverable than at the same time of any preceding year, and there is every probability that it will be both more general and more de-
structive. In the same season too, according to my observation, it is in no degree influenced by it—for instance, this year it showed itself in my neighbourhood in the most alarming manner for the first time, when the corn and cotton had begun to suffer from a dry spell of two or three weeks. I have known it to stop for a considerable time in very wet weather, and to recommence its progress after the rains had ceased. It is earlier in its appearance this year than before, and I believe earlier last year than the preceding. This disease attacking at different times with different de-
grees of violence, I will not hazard the asser-
tion that its cause is uniformly distinguished by the same appearances. The first indication in very many cases is a dark brown or black spot on the bowl; in others, the whole exterior of the bowl seems to have passed at the same time from the green to the dark brown, and is saturated with moisture, and whilst it is evi-
dently suffering the process of fermentation, will open and deliver the wool uninjured. It is the same disease, exhibiting different features as it rages with greater or less degree of acri-
mony. It attacks the bowl in every stage from the first formation to that stage of its perfection which immediately precedes development.

"It has visited all varieties of soil and treated all alike. I do not mean that every plantation,
GOSSYPIUM.

or that every district of country, shared, in equal degree, the evils of this visitation. Some have escaped with more or less injury; but I am inclined to think that these who have escaped with least, will have their turn. The mode of cultivation makes no difference. There are two modes, the close and the strictest. The last has become fashionable of late; but I have seen the isolated plant and the one environed by the branches and overshadowed by the top of its neighbours, equally afflicted.

"I think you will conclude from the foregoing statement that rain or sunshine, hill or dale, soil, destruction of the garden earth, cultivation whatever the mode, stop not its march. We recur, therefore, to the existing controversy, Is insect or constitutional disorder of the plant the cause of rot? If insect, would they not be seen in great numbers and where their ravages are greatest? I have examined fields most injured by rot, and could never make any discovery of them; besides, the year of drought is the year of insect—the rot made its appearance in a year of wet—since that, it seems not to have been afflicted by either wet or dry weather."

There are some who think that the rot in cotton is neither a constitutional disease of the plant nor the result of destructive insects attacking the pod, but that the true cause is a fungus production or parasite, similar to that which produces the mildew, rust, and blight in wheat. As yet no remedy for this evil has been found deserving confidence, unless it be the substitution of the Petit-Gulf variety, which is confidently asserted to answer the purpose, by a correspondent of the Farmer's Register, who had given a two years' trial with perfect success. (Vol. ii. p.548.) He believes the rot—which, he says, is most prevalent in rainy seasons, and in humid states of the atmosphere—is the result of insect depredation, and thinks the new kind of cotton not agreeable to the insect.

The upland cotton is sometimes very much injured by a disease called the rust, and also suffers from the depredations of a greenish caterpillar which eats into the bowl and causes great destruction. The Mexican cotton was introduced mainly with the hope of its resisting the ravages of the caterpillar. The cotton whilst young is also apt to be infested with plant lice (Aphidinus). The remedies adopted against these are of the most opposite kinds, namely, allowing the grass to grow for the purpose of inviting the insects from the cotton, or working and clearing the ground with extra attention.

The cotton planters of Upper Mississippi do not suffer much from the rot, the caterpillar, or the rust, the greatest enemies of their crops being the louse, snails and slugs, and a disease of the stem of the plant commonly known by the homely name of sore-shin. This comes on when the plants are small and only have the third leaf, and is supposed to be the effect of wet weather and heavy, packing rains. In Louisiana the planters complain of their losses from the rot, rust, boll-worm, army-worm, and rains. Such are some of the difficulties, in addition to those commonly met with from atmospheric agencies, against which the cotton crop in the United States has to contend, and by which it is rendered exceedingly precarious.

GOURD (Lagenaria vulgaris, calabash). The gourd family flourish well in the United States in the open air, and the several varieties make up a large amount of the produce of the gardens and farms. The large bottle gourds are extremely useful among the country people by whom they are used as dippers. Some of them are so large as to hold nearly a gallon. They are light and with good usage may last for months and even for several years. If, after a few gourds have set, the ends are pinched off the vine will continue bearing much larger and better. Some kinds of gourds are cultivated for their beauty. The fruit of the bi-coloured variety is small and very pretty, deep green on one side and yellow on the other. There are several other varieties, distinguished by the shape and appearance of the fruit. It is believed, says Dr. Darlington, that there are no native species of gourd in the United States, though the plant is said to have been cultivated by the aborigines, from time immemorial. (Flora Cestrica.)

RAFTING. In horticulture, the operation of affixing one portion of a plant to another in such a manner as that a vital union may take place between them. Grafting has been practised from the remotest antiquity; but its origin and invention are differently related by naturalists. Grafting may be performed both with herbaceous and ligneous plants; but, in practice, it is chiefly confined to the latter, and more especially to the propagation of esteemed varieties of fruit trees. A grafted plant consists of two parts; the stock or stem, which is a rooted plant fixed in the ground, and the scion, sometimes, but erroneously, termed the graft, which is a detached portion of another plant to be affixed to it. The operation of grafting can only be performed within certain physiological limits; but what these are, science has not yet absolutely determined. In general, all the species of one genus may be grafted on another reciprocally; but this is not universally the ease, because the apple cannot be grafted on the pear, at least not for any useful purpose. Indeed, it may be questioned whether all the species of a natural order, or at least a tribe, may be grafted on one another; but this does not hold good universally. The reverse of this doctrine, however, viz. that the species belonging to different natural orders cannot be grafted on another, holds almost universally true; and, therefore, a safe practical conclusion is that, in choosing a stock, the nearer in affinity the species to which that stock belongs is to the scion, the more certain will be the success.

Grafting is one of the most important operations in horticulture, as affording the most eligible means of multiplying and perpetuating all our best varieties of fruit trees, and many kinds of trees and shrubs not so conveniently propagated by other means. Varieties of fruits are originally procured by selection from plants raised from seed, but they can only be perpetuated by some mode which continues the individual; and though this may be done by cuttings and layers, yet by far the most eligible
mode is by grafting, as it produces stronger plants in a shorter time than any other methods. Grafting is performed in a great many different ways; but the most eligible for ordinary purposes is what is commonly called splice-grafting, whip-grafting, or tongue-grafting. In executing this mode, both the scion and the stock are pared down in a slanting direction; afterwards applied together, and made fast with strands of bass matting, in the same manner as two pieces of rod are spliced together to form a whiphandle. To insure success, it is essentially necessary that the albumen, or inner bark of the scion, should coincide accurately with the inner bark of the stock; because the vital union is effected by the sap of the stock rising up through the soft wood of the scion. After the scion is tied to the stock, the graft is said to be made; and it only remains to cover the part tied with a mass of tempered clay, or any convenient composition that will harden the air. Some of the other modes practised are termed cleft, or slit-grafting, crown-grafting, cheek-grafting, side-grafting, and grafting by approach, or inarching.

The season for performing the operation is, for all deciduous trees and shrubs, the spring, immediately before the movement of the sap. The spring is also the most favourable period for evergreens: but the sap in this class of plants being more in motion during winter than that of deciduous plants, grafting, if thought necessary, might be performed at that season.

Grafting Timber Trees.—The oak, ash, horn-beam, and hazel, may be grafted, but there is a little difficulty in grafting some of the hard-wood trees. On the oak may be worked its striped-leaved variety of pedunculata, and the varieties of sessiliflora. The limebeam, and other oaks of that kind, require to have the Turkey oak for a stock; and the evergreen, or ilex oaks, must have their own species. The common ash will take with the orme, and any of the hairy varieties of true ashes, such as the Chinese and entire-leaved. The hcearbeam may be used as a stock for Carpinus orientalis, and the cut-leaved sort; but the scions must be from two years old wood. The purple-leaved hazel may be grafted on the hazel stocks.

Grafting by approach, or inarching, is a mode of grafting, in which, to make sure of success, the scion is not separated from the parent plant till it has become united with the stock. Inarching is chiefly practised with oranges, myrtles, jasmines, walnuts, firs, &c., which do not flourish by the common mode of grafting.

Grafting herbaceous plants differs in nothing from grafting such as are of a woody nature, excepting that this operation is performed when the stock and scion are in a state of vigorous growth. The only useful purpose to which this mode has been hitherto applied is, that of grafting the finer kinds of dahlias on tubers of the more common and vigorous-growing sorts. In the Paris gardens, the tomato is sometimes grafted on the potato, the cauliflower on the broccoli, and one gourd on another, as matter of curiosity.

Grafting the herbaceous shoots of woody plants is scarcely known among English gardeners; but it has been extensively employed by French nurserymen, and even in some of the royal forests of France. The scions are formed of the points of growing shoots; and the stocks are also the points of growing shoots, cut or broken over an inch or two below the point, where the shoot is as brittle as asparagus. The operation is performed in the cleft manner; that is, by cutting the lower end of the scion in the form of a wedge, and inserting it in a cleft or slit made down the middle of the stock. The finer kinds of azaleas, pines, and firs, are propagated in this way in the French nurseries; and thousands of Pinus larix have been so grafted on Pinus sylvestris in the forest of Fontainiebeau. At Hopetoun House, near Edinburgh, this mode of grafting has been successfully practised with Abies Smithiana, the stock being the common spruce fir.

GRAIN. (French graine; Ital. gran; Norv. grønn, corn.) The general name of all kinds of corn. See Wheat, Maize, Oats, Barley, Corn-Laws, &c. It means, in another sense, the seed of any fruit, the direction of the fibres of wood, &c.; the form of the surface, with regard to roughness or smoothness; or a minute particle. In this article I have only to insert those facts with regard to grain that could not be well included under other heads. It has been calculated that the total consumption of wheat and other grain in the United Kingdom is, in a year—of wheat 12,000,000 quarters, and of other grain 40,000,000 quarters, equal to 52,000,000 quarters, or per day 154,762 quarters. (Quart. Journ. of Agr. vol. iii. p. 1063.) Of this about 25,000,000 bushels of barley are consumed in malt by the breweries and distilleries.

Dr. Colquhoun has calculated that the annual consumption of grain in England by each person is as follows:

<table>

</table>
GRAINS.

The amount of the different grains produced in the United States, collectively, and also for each of the states, has been given under the heads of Agricultural Returns. Tabular statements under the various heads will show the prices of grain in the United States for a series of years. See Wheat, Corn, Oats, &c.

GRAINS, BREWERS', are very extensively used in the feeding of live-stock. They consist chiefly of the husk, and other insoluble matters of the corn employed in the operation of brewing. When speaking of the large dairies of the metropolis, Mr. Youatt remarks, "The principal food of the cows in all these is grains; and as the brewing seasons are chiefly in autumn and spring, a stock of grain is generally laid in at these seasons for the rest of the year. The grains are laid up in pits lined with brick-work, set in cement, from ten to twenty feet deep, and of any convenient size. They are firmly trodden down, and covered with a layer of moist earth, eight or nine inches thick, to keep out the rain and frost in winter, and the heat in summer. A cow consumes about a bushel of these grains daily, the cost of which is from fourpence to fivepence, exclusive of carriage and preservation. The grains are, if possible, thrown into the pit while warm and in a state of fermentation, and they soon turn sour; but they are not liked the worse by cattle on that account: and the air being perfectly excluded, the fermentation cannot run on to putrefaction. The dairymen say that the slow and slight degree of fermentation which goes on tends to the greater development of the saccharine and nutritive principle, and they will have as large a stock on hand as they can afford, and not open the pits till they are compelled. It is not uncommon for two years to pass before a pit of grains is touched: and it is said that some have lain nine years, and been perfectly good at the expiration of that period. The grains from a large ale brewery are the most nourishing; those from the porter brewers, not so good; and those from the little ale brewers hardly worth having. It is found by the distillers that rough clover chaff, mixed with grains and wash, will fatten to any extent." (On Cattle, pp. 255—264.)

The British Husbandry.
by the same kind of insects in the United States.

"The European grain-moth, (Tinea granella), in its perfected state, is," says Dr. Harris, "a winged insect, between three and four-tenths of an inch, elongated from the head to the tip of its wings, and expands six-tenths of an inch. It has a whitish tuft on its forehead; its long and narrow wings cover its back like a sloping roof, are a little turned up behind, and are edged with a wide fringe. Its fore-wings are glossy like satin, and are marbled with white or gray, light brown, and dark brown, or blackish spots, and there is always one dark, square spot near the middle of the outer edge. Its hind-wings are blackish. Some of these winged moths appear in May, others in July and August, at which times they lay their eggs; for these are two broods of them in the course of the year. The young from the first laid eggs come to their growth and finish their transformations in six weeks or two months; the others live through the winter, and turn to winged moths in the following spring. The young moth-worms do not burrow into the grain, as has been asserted by some writers, who seem to have confounded them with the Angoumois grain-worms; but, as soon as they are hatched, they begin to gnaw the grain and cover themselves with the fragments, which they line with a silken web. As they increase in size, they fasten together several grains with their webs, so as to make a larger cavity, wherein they live. After a while, becoming uneasy in their confined habitations, they come out and wander over the grain, spinning their threads as they go, till they have found a suitable place wherein to make their cocoons. Thus, wheat, rye, barley and oats, all of which they attack, will be found full of lumps of grain cemented together by these corn-worms, as they are sometimes called; and when they are very numerous, the whole surface of the grain in the bin will be covered with a thick crust of webs and of adhering grains. These destructive corn-worms are really soft and naked caterpillars, of a cylindrical shape, tapering a little at each end, and are provided with sixteen legs, the first three pair of which are conical and jointed, and the others fleshy and wart-like. When fully grown, they measure four or five-tenths of an inch in length, and are of a light ochre or buff colour, with a reddish head. When about six weeks old they leave the grain and get into cracks, or around the sides of corn-bins, and each one then makes itself a little oval pod, or cocoon, about as large as a grain of wheat. The insects of the first brood, as before said, come out of their cocoons, in the winged form, in July and August, and lay their eggs for another brood: the others remain unchanged in their cocoons through the winter, and take the chrysalis form in March or April following. Three weeks afterwards, the shining brown chrysalis form, itself partly withdrawn from the cocoon, by the help of some little sharp points on its tail, and bursts open at the other end, so as to allow the moth therein confined to come forth.

"The foregoing account, drawn from European authorities, will probably enable readers to determine whether these destructive insects are found in the United States. From various statements, deficient, however, in exactness, that have appeared in some of our agricultural journals, I am led to think that this confidence may be exactly like it in its habits, prevails in the different country, and that it has generally been mistaken for the grain-weevil, which it far surpasses in its devastations. Many years ago I remember to have seen oats and shelled corn (maize) affected in the way above described, and have observed seed-corn, hanging in the ears, to have been attacked by insects of this kind, the empty chrysalids of which remained sticking between the kernels; but, for some time past, no opportunity for further investigation has offered itself." See Cox-Mor.
Whether wheat and other grain suffers to any extent in this country, from either of these weevils, I have not been able to ascertain, as the accounts given of the ravages of the insects supposed to be weevils are rarely accompanied by any description of them in their different states.

"Rice is attacked by an insect closely resembling the wheat-weevil, from which, however, it is distinguished, by having two large red spots on each wing cover; it is also somewhat smaller, measuring only about one-tenth of an inch in length, exclusive of the snout. This beetle, the Calandra (Sitophila) Orzyae, or rice-weevil, is not entirely confined to rice, but predares upon maize or Indian corn also. I have seen stored Southern corn swarming with them; and, should they multiply and extend in this section of the country, they will become a source of serious injury to one of the most valuable of our staple productions. It is said that this weevil lays its eggs on the rice in the fields, as soon as the grain begins to swell. If this indeed be true, we have very little to fear from it here, our Indian corn being so well protected by the husks that it would probably escape from any injury, if attacked. On the contrary, if the insect multiply in stored grain, then our utmost care will be necessary to prevent its multiplying from infecting our own garners. The parent beetle bores a hole into the grain, and drops therein a single egg, going from one grain to another till all her eggs are laid. She then dies, leaving, however, the rice well seeded for a future harvest of weevil-grubs. In due time the eggs are hatched, the grubs live securely and unseen in the centre of the rice, devouring a considerable portion of the substance, and when fully grown they gnaw a little hole through the end of the grain, artfully stopping it up again with particles of rice-flour, and then are changed to pupae. This usually occurs during the winter; and in the following spring the insects are transformed to beetles, and come out of the grain. By winnowing and sifting the rice in the spring, the beetles can be separated, and should then be gathered immediately and destroyed." (Harris) See Corn-Moth.

GRANARY. A place where corn is stored. These have of necessity been constructed in all ages of the world, and of different materials, according to the facilities afforded for their construction by the neighbourhood in which they are placed; in England they are commonly, for farming purposes, made of wood or brick. In Sicily the public granaries are in some places hollowed out of the solid rock. According to a modern authority (Brit. Hist. vol. i. p. 94), "The best situation for a granary is over the thrashing-floor. It may be easily secured from vermin; and requiring only six feet in height, it will not intercept materially with the bays of the barn, especially if they be loaded through the gables. A trap-door in the floor, with a rope and pulley, raises and lowers the load in the most easy manner, besides securing it more effectually from depredators; and strong wired windows at each end ventilate it sufficiently. The most general mode, however, of forming granaries, is to erect them of timber, and place them upon pilars of stone or wood." It has been suggested that corn kept in granaries would be effectually protected from the ravages of the weevil, by mixing with it a small quantity of common salt. See Corn-Moth, Weevil, and Con.

GRAPe-Vine. See Vine.

GRAPe-Vine CATERPILLAR. Every person, says Dr. Harris, who has paid any attention to the cultivation of the grape-vine in this country, must have observed upon it, besides the large sphynx caterpillars that devour its leaves, a small blue caterpillar transversely banded with deep orange across the middle of each ring, the bands being dotted with black, with the head and feet also orange, the top of the eleventh ring somewhat bulging, and the forepart of the body bunched up when the creature is at rest. These caterpillars begin to appear about the middle of July, and others are hatched afterwards, as late, perhaps, as the middle of August. When not eating, they generally rest upon the under-sides of the leaves, and, though many may be found on one vine, they do not associate with each other. They live on the common creeper as well as on the grape-vine. They eat all parts of the leaves, even to the midrib and stalks. When fully grown, and at rest, they measure an inch and a half in length, and a width of about half an inch. The length of an inch and a half or more. Towards the end of August they begin to disappear, and no more will be found on the vines after September. They creep down the vines in the night, and go into the ground, burying themselves three or four inches deep, and turn to chrysalids without making cocoons. The chrysalis is dark-brown, and rough, with elevated points. The moths begin to come out of the ground as soon as the 25th of June, and others continue to appear till the 20th of July. Though of small size, they are very beautiful, and surpass all others of the family in delicacy of colouring and design. The name of this moth is Eudryas grae, the first word signifying beautiful wood nymph, and the second agreeable or pleasing. The antennae are rather long, almost thread-like, tapering to the end, and not feathered in either sex. The fore-wings are pure white, with a broad stripe along the front edge, extending from the shoulder a little beyond the middle of the edge, and a broad band around the outer hind margin, of a deep purple-brown colour; the band is edged internally with olive-green, and marked towards the edge with a slender wavy white line; near the middle of the wing, and touching the brown stripe, are two brown spots, one of them round and the other kidney-shaped; and on the middle of the inner margin there is a large triangular olive-coloured spot; the under-side of the same wing is yellow, and near the middle there are a round and a kidney-shaped black spot. The hind-wings are yellow above and behind; on the upper-side yellow, a broad purple-brown hind border on which there is a wavy white line, and on the under-side with only a central black dot. The head is black. Along the middle of the thorax there is a broad crest-like stripe of black and pearl-coloured glittering scales. The shoulder-covers are white. The upper side of the abdomen is yel

567
GRASS.

low, with a row of black spots on the top, and another on each side; the under-side of the body, and the large muff-like tufts on the fore-legs, are white; and the other legs are black. This moth rests with the fore-legs, like a steep roof over its back, and its fore-legs stretched forward like a Ctenura. It expands from one inch and a half to one inch and three quarters.

*Eudryas unio*, of Hübnér, the pearl Eudryas, as its name implies, is a somewhat smaller moth, closely resembling the preceding, from which it differs in having the stripe and band on its fore-wings of a brighter purple-brown colour, the round and kidney-shaped spots contiguous to the former also being of the olive-coloured edging of the band wavy, with a powdered blue spot between it and the triangular olive-coloured spot on the inner margin, and a distinct brown spot on the inner hind angle of the posterior wings; all the wings beneath are broadly bordered behind with light brown, and the spots upon them are also light brown. It expands from one inch and three-eighths to one inch and a half. This species has been taken in Massachusetts, but it is rare, and the caterpillar is unknown to me. (*Herbaria*).

GRASS (Goth. *græs*; *græs*, from *gro*, to grow, to sprout). The common herbage of the field on which cattle feed.

The grasses, it has been often and well said, "are nature's care." There is, perhaps, no class of the vegetable world so little understood as this. "Grass," says Professor Martyn, "vulgarly forms one single idea, and a husbandman, when he is looking over his enclosure, does not dream that there are upwards of 300 species of grass, of which 30 or 40 may be at present under his eye. They have scarcely had a name besides the general one till within these 20 years; and the few particular names which have been given them are far from having obtained general use, so that we may fairly assert that the knowledge of this most common and useful tribe of plants is yet in its infancy." (Letters on Botany, xiii.)

It is certain, however, that since Professor Martyn wrote, much has been done to add to our knowledge of the grasses. These grow in all parts of the world promiscuously, and without cultivation, affording both directly and indirectly the means of subsistence to man. Europeans live chiefly upon wheat, rye, and barley, to which list their American descendants have added maize or Indian corn.

The cultivation of the earth," says Professor Johnson, "preceded the improvement of the intellect, and was the herald of civilization. It is remarkable that we have no direct criterion of the origin of many of those grasses met with everywhere in cultivation, as none of them are, to any extent, found wild. Some travellers have thought that barley was indigenous to Tartary, rye to Crete, and wheat to Asia, but these might have been diffused from some cultivated some years previously. Corn is not only the support of man, but the grasses are the subsistence of the animals which form his nutriment. The nutritive quality of grasses is principally owing to the sugar which they contain, and of which some English grasses contain large quantities, but the sugar cane is the only grass that is exclusively cultivated for obtaining this article for commerce. The grasses are applied to a vast variety of important mechanical purposes; they are found in every part of the world, from the Poles to the Equator; on the land, as well as floating on the water, and are the universal food of animals." The botanist has shown that there are more than 130 distinct native species and varieties of grass in Great Britain, all possessing distinct properties, and varying in their degrees of value to the farmer, from the most worthless, to those on which his successful farming chiefly depends. The researches, too, which have been made by the late Duke of Bedford, and carried on during a series of years in the grass garden at Woburn, have added very materially to our stock of knowledge concerning these plants; for, instituted with a public object, and under the careful and skilful management of one of my earliest correspondents, the late Mr. George Sinclair, the results were given by him to the public in the *Hortus Gramenius Woburnensis*, a valuable and elaborate work, to which I am chiefly indebted for the matter of this and other articles upon the grasses. The manner in which these celebrated experiments of the Duke of Bedford were conducted, is thus described:

"Spots of ground, each containing 4 square feet, in the garden at Woburn Abbey, were enclosed by boards in such a manner that there was no lateral communication between the earth included by the boards, and that of the garden. The soil was removed in these enclosures, and new soils supplied; or mixtures of soils were made in them, to furnish as far as possible to the different grasses those soils which seem most favourable to their growth, a few varieties being adopted for the purpose of ascertaining the effect of different soils on the same plant. The grasses were either planted or sown, and their produce cut and collected, and dried at the proper seasons, in summer and autumn, by Sinclair, his Grace's gardener. For the purpose of determining, as far as possible, the nutritive powers of the different species, equal weights of the dry grasses or vegetable substances were acted upon by hot water till all their soluble parts were dissolved; the solution was then evaporated to dryness by a gentle heat in a proper stove, and the matter obtained carefully weighed. This part of the process was likewise conducted with much address and intelligence by Sinclair, by whom the various details and calculations were furnished. The dry extracts supposed to contain the nutritive matter of the grasses, were sent to me for chemical examination. The composition of some of them is stated minutely; but it will be found, from the general conclusions, that the mode of determining the nutritive power of the grasses, by the quantity of matter they contain soluble in water, is sufficiently accurate for all the purposes of agricultural investigation." (Agr. Chem. app.)

In regard to the description of soils—1st. By loam, is meant any of the earths combined with decayed animal or vegetable matter. 2d. Clayey loam, when the greatest proportion is
GRASS.

clay. 3d. Sandy loam, when the greatest proportion is sand. 4th. Brown loam, when the greatest proportion consists of decayed vegetable matter. 5th. Rich black loam, when sand, clay, animal, and vegetable matters are combined in unequal proportions, the clay, greatly divided, being in the least proportion, and the sand and vegetable matter in the greatest. The terms light sandy soil, light brown loam, &c., are varieties of the above, as expressed.

The systematic arrangement of grasses is a difficult and unsatisfactory task, and has occupied the attention of many botanists. The most recent work upon the subject is Kunkel’s *Agrostographia*, published at Berlin in 1836.

In choosing the mixture of grass seeds most valuable for the farmer’s soil, many considerations must be taken into calculation; not only the nature of the soil, and the supply of water to which its habits are best adapted, but also the objects which the farmer has in view.

Thus, the meadow foxtail (*Alopecurus pratensis*), although an early, nutritive, and productive grass, requires more than two years to arrive at perfection; it is, therefore, better adapted for permanent pasture than for the alternative husbandry. And then, again, the meadow cat’s-tail or timothy (*Phleum pratense*), although remarkable for producing the most nutritious culms of all the grasses, and that, too, in a considerable bulk, yields a far lower yield of very little value. Valuable, therefore, as it is for hay, it is of little consideration for feeding purposes if sown by itself; it must, therefore, be combined with other grasses. So the cock’s-foot or orchard grass (*Dactylis glomerata*), which soon arrives at perfection, and yields early and late a profusion of leaves, which are highly nutritious, has culms or stalks of little value; it is a grass, therefore, most profitable for feeding purposes. “Under these different relations, therefore,” says Mr. G. Sinclair, “a grass should be considered, before it is absolutely rejected, or indiscriminately recommended.”

The knowledge of the relative nutritive matters contained in different grasses, will not only be a highly important object of research, as connected with their feeding properties, but as throwing considerable light on the powers of the different grasses to exhaust or impoverish the soil, a question which I shall examine more at length under the head “Rotation of Crops.” A more intimate and exact knowledge, with regard to the position of plants, may be derived from even an examination of their external appearance than many persons would deem possible. The following are some of the general results of the observations of Sinclair:

1. Grasses which have culms with swollen joints, leaves thick and succulent, and flowers with downy husks, contain greater proportions of sugar and mucilage than those of a less succulent nature.

2. When the structure is of a light glaucous colour, the sugar is generally in excess.

3. Grasses which have culms with small joints; flowers pointed, collected into a spike or spike-like panicle; leaves thin, flat, rough, and of a light green colour, contain a greater proportion of extractive matter than others.

4. Grasses which have culms furnished with numerous joints; leaves smooth and succulent; flowers in a spike or close panicle; florets blunt and large, contain most gluten and mucilage.

5. When this structure is of a glaucous colour, and the florets woolly, sugar is in the next proportion to mucilage.

6. Grasses which have their flowers in a panicle, florets pointed or awned, points of the culm smooth and succulent, contain most mucilage and extractive.

7. Grasses with flowers in a panicle; florets thinly scattered, pointed, or furnished with long awns; culms lofty, with leaves flat and rough, contain a greater proportion of saline matter and bitter extractive.

8. Grasses with strong, creeping roots, culms few, leaves flat and rough, flowers in a spike, contain a greater proportion of bitter extractive, and mucilage.

In the first part of April 1920 grains of the leaves of the following grasses, &c, afforded, according to Mr. G. Sinclair, the following proportions of nutritive matter:

The chemical composition of the grasses varies materially in the progress of their growth, a fact well worthy of the farmer’s serious attention in more ways than one. “I found,” says Davy, “in all the trials I made, the largest quantity of truly nutritive matter when the seed was ripe, and least bitter extract and saline matter; most extract and saline matter in the autumnal crop, and most saccharine matter in proportion to the other ingredients in the crop cut at the time of flowering. I shall give one instance:

> “100 parts of the soluble matter obtained from the round paniced cock’s-foot grass (Dactylis glomerata), cut in flower, afforded of

| Sugar | 18 |
| Muelage | 66 |
| Extract, saline matters, &c. | 100 |

“100 parts of the soluble matter from the seed crop, afforded of

| Sugar | 11 |
| Muelage | 30 |
| Extract, &c. | 100 |

“100 parts of soluble matter from the aftermath crop gave of

| Sugar | 11 |
| Muelage | 59 |
| Extract | 30 |

(Refs. of Agr. Chem. 477.)

The seeds of the Grasses.—The ripening of the seeds of the essential grasses (says Sinclair), takes place at three different periods of the season, or, if they are classed according to the time about which each species ripens its seed, they will form three divisions or groups; the first, consisting of the earliest species, perfect their seed about the end of June—such as the sweet-scented vernal-grass and the narrow-leaved meadow-grass: the second consisting of the sheep’s-fescue grass, and others, about the end of July; and the third, such as the flax-grass, and others, about the first or second week in September, as may be seen from the following

Table of the average periods at which different species of Grasses ripen their seed, drawn up by the late Mr. G. Sinclair, from the details of ten years’ practical observation and experiment. (Allorance must be made for difference of climate between England and America.)

| Annual meadow-grass (PoA annua), Pl. 6, e, from April 10 to frosts. | Sweet-scented vernal grass (Anthæanthum odoratum), Pl. 30, 10 to 20. | Soft annual bromegrass (Bromus mollis), Pl. 7, b, 12 to 20.
|---|---|---|
| Silver-hair, hair-grass (Aira caespitosa) | 15 to 20. | Bitter vernal grass (Anthæanthum odoratum) | 15 to 20.
| Wheateed vernal-grass (Elymus trilobatus) | 20 to 20. | Bitter vernal-grass (Elymus trilobatus) | 15 to 20.
| Narrow-leaved cotton-grass (E. caespitulosus) | 20 to 20. | One-flowered melic-grass (Melica uniflora) | 18 to 24.
| Millet-grass (Milium effusum) | 20 to 25. | Alpine meadow-grass (PoA alpina), Pl. 6, 18 to 24.
| Narrow-leaved meadow-grass (PoA annua), Pl. 6, 18 to 24. | Blue meadow-grass (Ihæeria caerulea) | 18 to 24.
| Meadow foxtail-grass (Alopecurus pratensis) | 18 to 24. | Meadow foxtail-grass (Alopecurus pratensis) | 18 to 24.
| Sweet-scented soft-grass (Abregera generalis) | 18 to 24. | Barley-like fescue (Festuca verna, hordeiformis) | June 20 to July 50.
| Woolly soft-grass (Holcus lanatus) | 18 to 24. | Small-flowered oat-grass (Avena palustris) | 4 to 10.
| Field or meadow broom-grass (Bromus arenosus) | 7. | Small-flowered oat-grass (Avena palustris) | 4 to 10.
| Jointed hair-grass (Alopecurus geniculatus) | 7 to 26. | Spiked hair-grass (D. zarinctorum) | 15 to 25.
| Bulbous meadow-grass (PoA bulbosa) | 11. | Yellow oat-grass (Avena palustris) | 15 to 25.
| Blue meadow-grass (PoA palustris) | 18 to 25. | Nodding paniced bent-grass (Bromus tectorum) | 13 to 17.
| Crested dog’s-tail (Cynosurus crispus) | 16 to 30. | Horn of plenty (Cenonepia cucullata) | 16.
| Round-horned cock’s-foot grass (Dactylis glomerata) | 19 to 20. | Perennial ryegrass (Lolium perenne) | 25 to 30.
| Glacious cock’s-foot grass (D. glaucescens) | 20 to 30. | Striped American variety (D. Americana var.) | 22 to 30.
| Striped meadow-grass (D. pratense) | 20 to 30. | Wood fescue (Festuca dumetorum) | 19 to 30.
| Russell-grass (Lolium Russellianum) | 20 to 30. | Reflexed meadow-grass (PoA distans) | 20 to 30.
| Red meadow-grass (L. rigidus) | 20 to 30. | Rigid meadow-grass (L. rigidus) | 20 to 30.
| Rough-stalked meadow-grass (L. Trilantis) | 20 to 50. | Smooth meadow-grass (PoA pratensis), Pl. 6, 15 to 17.
| Fescue var. | 15 to 20. | Small-flowered oat-grass (Avena palustris) | 4 to 10.
| Creeping fescue-grass (Festuca rubra) | 12 to 25. | Common quaking grass (Brizia media) | 15 to 20.
| Medlilval clover (Trefolium Medilvum officinale) | 14 to 15. | Upright broom-grass (Bromus erectus) | 20 to 25.
| Bush fescue (Festuca pratensis) | 15 to 25. | Sheep’s fescue-grass (Festuca ovina) | 6 to 19.
| Early hair-grass (A. pratensis) | 20 to 30. | Water hair-grass (A. aquatica) | 20 to 30.
| Cow’s-tail fescue (F. pratensis) | 20 to 30. | Creasted hair-grass (A. cristata) | 20 to 30.
| Giant broome-grass (Bromus giganteus) | 20 to 30. | Slender oat-grass (Arenna brizoides) | 20 to 30.
| Eastern oat-grass (A. orientalis) | 25 to 35. | Woolly broom-grass (B. distachus) | 30 to 35.
| Meadow oat-grass (A. pratensis) | 21 to 30. | Wall broom-grass (B. diandrus) | 25 to 31.
| Broom grass (B. distachus) | 30 to 35. | Tongue-shaped broom-grass (B. fluitans) | 20 to 30.
| Small paniced meadow-grass (E. paniculatus) | 21 to 30. | Flat-spaked broom-grass (B. unioloides) | 21 to 30.
| Wood meadow-grass (Milia alpina) | 21 to 30. | Wood meadow-grass (Milia ephusus) | 21 to 30.
| Hard fescue-grass (F. dorsileus) | 20 to 30. | Brumus crassutus) | 20 to 30.
| Creasted broome-grass (B. crassus) | 20 to 30. | Slender fescue-grass (Festuca gracillima) | 20 to 30.
| Slender fescue-grass (F. verna tenuis) | 20 to 30. | Slender fescue-grass (F. verna tenuis) | 20 to 30.
| Meadow fescue-grass (F. pratensis) | 5 to 10. | V给她prous fescue (F. vespertina) | 20 to 30.
| Slender fescue-grass (F. verna tenuis) | 20 to 30. | Sand canary-grass (Phalaris arenaria) | 20 to 30.
| Ciliated meadow-grass (Altema ciliata) | 30 to 35. | Nerved meadow-grass (PoA nervosa) | 20 to 30.
| Rye-like grass (Festuca lutea) | 21 to 30. | Lesser meadow cat’s-tail (Phleum pratense) | 25 to 30.
| Flax-grass-like fescue (Festuca lutea) | 20 to 30. | Linear-sparked (Cynosurus crusiformis) | 21 to 30.
| Wood meadow-grass (PoA dormitoria) | 20 to 30. | Chickweed cat’s-tail (Phleum pratense) | 20 to 30.
| Bulbous jointed cat’s-tail grass (Phleum nodatum) | 20 to 30. | Wood meadow-grass (PoA nervosa) | 20 to 30.
| Phentile meadow-grass (PoA pilosa) | 20 to 30. | Larger bird’s-foot trefoil (Lotus major) | 20 to 30.
| Grass nodding ear-grass (Lotus enteririus) | 20 to 30. | Smaller bird’s-foot trefoil (L. minor) | 20 to 30.
| Capan’s-tail fescue (Festuca Monia) | 20 to 30. | Capan’s-tail fescue (Festuca Monia) | 20 to 30.
| Sea-green meadow-grass (PoA caesia) | 20 to 30. | Way-bennet, wall-barley (Hordeum murinum) | 20 to 30.
| Welsh fescue-grass (Festuca Cambrica) Pl. 7, e | 20 to 30. | Upright vicia (Ficca striata) | 20 to 30.

GRASS.

GRASS.

Grass (Eriastrum digitatum) — 1
Brazilian grass (Eriastrum uncinatum) — 2
Decumbent meadow-grass (Eriastrum uncinatum) — 3
Sheep-wheat-grass (Eriastrum uncinatum) — 4
Siberian bent-grass (Eriastrum uncinatum) — 5
Bearded wheat-grass (Eriastrum uncinatum) — 6
Awnless wheat-grass (Eriastrum uncinatum var.) — 7
Common bent-grass (Eriastrum uncinatum) — 8
Upright mat-grass (Eriastrum uncinatum) — 9
Small spurious tare (Eriastrum uncinatum) — 10
Broad-leaved oat-grass (Eriastrum uncinatum) — 11
Hairy tare (Eriastrum uncinatum) — 12
Four-seeded tare (Eriastrum uncinatum) — 13
Dwarf meadow-grass (Eriastrum uncinatum) — 14
Prospective meadow-grass (Eriastrum uncinatum) — 15
Long-rooted clover (Eriastrum uncinatum) — 16
Wood bent-grass (Eriastrum uncinatum) — 17
Tall fescue-grass (Eriastrum uncinatum) — 18
Many-flowered barley-grass (Eriastrum multiforme) — 19
Philadelphia lyme-grass (Eriastrum Philadelphia) — 20
Sordid vetch (Ficaria sordida) — 21
Slender-leaved vetch (Ficaria sordida) — 22
Beardless tall oat-grass (Hoehn sordida muticus) — 23
Red grass (Bromus rubens) — 24
Bent's red grass (Bromus rubens) — 25
Foxtail-like fescue (Fescue laterale) — 26
Hedgehog lyme-grass (Eriastrum latestral) — 27
Hedgehog barley-grass (Eriastrum latestral) — 28
Jointed lyme-grass (Eriastrum latestral) — 29
Golden oxi (Eriastrum latestral) — 30
Festuca ovina (Eriastrum latestral) — 31
Meadow barley-grass (Hordeum pratense) — 32
Narrow-leaved bromes (Bromus angustifolius) — 33
Slender rye-grass (Lolium temulentum) — 34
Speckled bent-grass (Bromus lacinifolius) — 35
Sainfoin (Onobrychis sativa) — 36
Winged barley-grass (Bromus pinnatus) — 37
Bent's red grass (Bromus pinnatus) — 38
Bundled bent (Bent vulgaris fasciculata) — 39
Couch grass (Eriastrum rigida) — 40
Wood vetch (Ficaria sordida) — 41
Tuffed vetch (Ficaria tuffa) — 42
Foxtail oat-grass (Avena alopecuroides) — 43
Awnless brown bent (Agrostis canina var. mutica) — 44
Couch bent-grass (Agrostis alba) — 45
Finch grass (Bent stolonifera) — 46
And many others. — 47
American cock's-foot (Dactylis glomerata) — 48
Stiff wheat-grass (Eriastrum rigidum) — 49
Among or six or others. (Sinclair's Hort. Gram. Web. p. 57.)

Of these grasses those regarded in England as the chief and most useful species and varieties are comprehended in the following list:

Agrostis canina. — Festuca rubra.
Agrostis stolonifera. — Festuca sylvatica.
Alpuescruus pratensis. — Festuca tenuifolia.
Aenua flavescent. — Holcus avenaceus.
Avena pratensis. — Holcus lanatus.
Bresia media. — Hordeum pratense.
Bromus arvensis. — Lolium perenne.
Cow-grass, or perennial red clover. — Poa annuu.
Cynosurus cristatus. — Poa candalis.
Dactylis glomerata. — Poa ferrilis.
Festuca cambrica. — Poa memoralis.
Festuca dandoiculata. — Poa nervata.
Festuca fluitans. — Poa pratensis.
Festuca glabra. — Poa trivialis.
Festuca heterophylla. — Red suckling.
Festuca hordeiformis. — Rib-grass.
Festuca ovina. — White or Dutch clover.
Festuca viridula. — Yarrow.

From some experiments, given in the Trans. 
Co., it would seem that the raising of the seeds of these artificial grasses is attended with 
considerable profit.

The late Mr. Blakie suggested a very excellent plan for saving the seeds of down grasses, 
or of those grasses which are peculiarly adapted for elevated dry soils (Farm. Journ. March 17, 1823), viz. to fence off a sufficient portion of these pastures, choosing such portions as have the best kind of grasses, and to mow these enclosures for seed in succession, at three, four, or more different periods of the season. By these means Mr. G. O. E. obtained the seeds of the early, midsummer, and late vegetating grasses will be obtained, and which could not, it is evident, be obtained by one mowing in one season. This is, he adds, "a highly valuable mode of obtaining the seeds of those grasses adapted for down; which, to cultivate separately for the seed, would be a fruitless undertaking. Fence the selected turf well, and early in the season, and prepare for mowing by picking the stones or rubbish from the surface, and by rolling. As the seeds ripen, employ a careful bird-watcher. Mow in dry, favourable weather. If the swaths are heavy, they should be turned with great caution, so as not to shake out the ripe seeds. As soon as the mowing is dry, the seed should be immediately threshed out on a close woven cloth in the field, and on a dry day; and when a certain portion of the later grasses ripen their seed, another mowing should be effected, and so on, until all the grasses in the enclosure have perfected their seed." (Hort. Grai, Web. p. 39, 40) "As every different soil," continues Sinclair, in another portion of his invaluable work, "produces grasses peculiar to itself, and as no other kinds can be established or cultivated upon it without first changing its nature to resemble that which produced the kind of grasses we wish to introduce; it becomes a point of the first importance in making experiments on different species of this numerous family of plants, and in stating results, to determine with sufficient accuracy the nature of the soil or different soils employed. The basis of every improvement in the cultivation of grasses is to sow the seeds of those species only which are adapted to the soil, or that which the nature of unsuitable soils is fitted for the growth of grasses most desirable to be cultivated; and, unless this important point is in the first place attended to, disappointment rather than success may be expected to follow the labours of the farmer."

1. Of the grasses of rich natural pastures.— Every farmer is aware that peculiar grasses are the productive tenants of his rich natural pastures, and that if these are ploughed up, and a course of grain crops taken from the soil, a considerable period elapses before the turf with which it was formerly covered can be restored. George Sinclair carefully noted this fact, and examined, and not altogether unsuccessfully, its cause. He observed that "the different grasses and other plants which compose the produce of the richest natural pastures are in number 25, and that from the spring to the end of autumn there is not a month that does not constitute the particular season of luxuriance of one or more of these grasses; hence proceeds the constant supply of rich, succulent herbage throughout the whole of the season, a circumstance which but seldom or never happens in artificial pastures, where the herbage consists
of two or three plants only. The plants which usually tenant the best natural pastures are the meadow fox-tail, round cock's-foot, meadow fescue, meadow cat's-tail, sweet-scented vernal grass, tall oat-like soft-grass, creeping vetch, rye-grass, field brome-grass, or Sulfur grass, meadow oat-grass: these yield the principal grass in the spring, and a chief portion of that of the summer. Then, again, we find the yellow oat-grass, meadow barley, crested dog's-tail, hard fescue, rough-stalked meadow-grass, smooth-stalked meadow-grass, woolly soft-grass, perennial red clover, white or Dutch clover, yellow vetch or meadow vetch, and the smooth fescue, which yield the principal portion of the summer and autumn produce. Lastly, we find the yarrow, creeping bent or fescue, marsh bent-grass, and creeping wheat-grass or couch, vegetating most vigorously in the autumn. Besides these," continues Sinclair, "in the richest natural pastures are invariably found the butter-cups (Ranunculus acris), rib-grass or ribwort plantain (Plantago lanceolata), and sorrel dock (Rumex acetosa)." Of these, however, except in cases of necessity, live-stock will only eat the rib-grass.

To examine the nature of the change produced on rich pasture land by a course of grain crops, Mr. Sinclair made the following valuable experiments.

"A space of 2 square yards of rich ancient pasture land was dug to the depth of 8 inches: 400 grains of this soil, freed from moisture and the green vegetable fibres, contained—

This soil was then cropped for 5 seasons alternately with 1, oats; 2, potatoes; 3, wheat; 4, carrots; 5, wheat. It was then examined, to ascertain what change it had undergone by bearing these crops. It appeared to consist of—

"Thus, the earthy portion of the soil had undergone but little change, but it had sustained a very considerable diminution of its decomposing vegetable and animal matters, particularly when it is considered that the turf also was incorporated with the soil. Manure was now for the first time applied, and, with the wheat stubble, dug in to the depth of 6 inches. The surface was then made fine with a rake, and sown with a mixture of the following grass seeds, at the rate of 5 bushels to the acre: Meadow fescue, meadow fox-tail, round cock's-foot, tall oat-like soft-grass, creeping vetch, rye-grass, meadow cat's-tail, crested dog's-tail, yellow oat, meadow oat, hard fescue, smooth-stalked meadow-grass, fertile meadow-grass, narrow-leaved meadow-grass, cow clover (Trifolium medium), Dutch or white clover, and forbin, marsh-bent. These were sown on the 28th of August, 1813. They all vegetated before the first week of October except the creeping vetch (Vicia sepium), which did not germinate till the autumn of 1814. Before the frost set in they had a top-dressing with a compost of rotten dung, lime, and vegetable mould, laid on in a fine and dry state, and rolled, and again rolled in February. The plants sprang earlier than those of the old pasture (a circumstance common to young plants in general). In the first week of July the produce was cut and weighed: it amounted to one-eighth more than that of the produce of the grain in its original state. The aftermath, however, of the seedling grasses weighed one-fifth less than that of the natural pasture. But in 1815, upon cutting and weighing the grass in the first weeks of June and August, and again in the middle of September, the total weight of these three crops exceeded that of the old turf exactly in the proportion of 9 to 2. (Hogg's Gras. Wob. 131.)

2. The grasses which are the natural tenants of dry sandy and elevated soils.—These, according to Sinclair, are the sheep's fescue, viviparous fescue, purple fescue, pubescent fescue, glaucous fescue, wall fescue, wall barley, fine bent, brown bent, lobed bent, rock bent, snowy bent, purple bent, tufted-leaved bent, waved hair-grass, feather-grass, slender fescue, hairy oat-grass, blue vermicul grass, upright mat-grass, blood-coloured panic-grass, green panic-grass, barren brome-grass, crested brome-grass, upright annual brome-grass, nodding brome-grass, Alpine meadow-grass, Alpine fescue-grass, blue moor-grass, crested hair-grass, paniced cat's-tail grass, reflexed meadow-grass, flat-stalked meadow-grass, meadow-barley, bird's-foot clover, larger bird's-foot clover, trefoil or nonsuch, sainfoin, soft brome-grass, creeping soft-grass, and white or Dutch clover. (Ibid. p. 256.)

"When these sandy upland soils are improved by the application of clay or marl, they are then capable of supporting a very superior description of grasses to these, and the following varieties," says Sinclair, "should be sown, for experience will prove that, under such circumstances, they are the best for that purpose." (Ibid. p. 337.)

3. The grasses of bogs, or other very moist soils.—These are commonly of the most worthless description of the cultivator: they are chiefly the marsh bent, awnless brown bent, awned creeping-bent, smaller-leaved creeping-bent, creeping-rooted bent, white bent, smooth fescue, tall fescue, turfy hair-grass, knee-jointed fox-
tail-grass, water hair-grass, water meadow-grass, long-leaved cotton-grass, and sheathed cotton-grass. (Hort. Wob. p. 340.)

4. The grasses of water meadows.—“All the superior perennial grasses,” observes Sinclair, “thrive under irrigation when the meadow is properly formed; the following species of grass I have invariably found to constitute the produce of the best water meadows.—Meadow foxtail, round-panicled cock’s-foot, field brome-grass, meadow fescue: these occupied the crowns and sides of the ridges. The furrows were stocked with the creeping bent, marsh bent, hard fescue, lesser variety of meadow cat’s-tail, woolly soft grass, rough-stalked meadow-grass, meadow fescue. A small admixture of other species were thinly scattered over every part of the ridge; these were meadow barley, yellow or golden oat, crested dog’s-tail, rye-grass, sweet-scented vernal-grass, tufted vetch, with a larger proportion of the tall oat-like soft-grass. The soil of the water meadows which produced the above grasses was either a deep active peat incumbent on a silicious sand, or a sandy loam, on a chalky or gravelly subsoil. In some irrigated meadows, where the ridges were formed nearly flat, and the soil consisted of a sandy loam on a retentive clayey subsoil, the following grasses constituted the chief produce:—Crested dog’s-tail, creeping-rooted soft-grass, rye-grass, meadow barley, tall oat-like soft-grass, sweet-scented vernal, and soft brome-grass.” (Ibid. p. 383.)

The grasses best adapted for the alternate husbandry also attracted the attention of George Sinclair; but he saw the difficulty of laying down any systematic rules which should be adapted for all soils and situations, and the demands for animal food: he hardly, therefore, made any very practical general observations. He gives us, however, among other valuable statements, the following little table of the relative value of three of the crops he had examined on similar soil:

6. Transplantation or incoulcation of turf.—This plan, which is one in certain situations, offering considerable advantages, is described in the Brit. Husb. vol. ii. p. 523, and by G. Sinclair, Hort. Grasm. Wob. p. 415. The mode of returning tillage land to permanent pasture, called transplanting, was originally invented by Mr. Whitworth, of Acre House, Lincolnshire, and it was first practised to any extent by Mr. John Bloomfield, of Warham, Norfolk. In laying down land to permanent pasture by this mode, it is essential that the soil should be free from the roots and seeds of weeds, and made perfectly clean by a summer fallow. The autumn is the best time for transplanting turf, and that as soon as the autumn rains have sufficiently moistened the turf to fit it for parceling off clean: the roots of the grasses thus get established before the commencement of warm weather in the spring. It is also essential that the turf should be selected or taken from the very best pasture, for otherwise weeds and inferior grasses will be propagated. If the field from which the turf is to be taken to make the new pasture, is intended to be a course of tillage crops, then the whole of the turf may be taken off and employed in forming the new pasture to the required extent. But should the field be required to remain in permanent pasture, a portion only of the turf must be taken from the field, and a sufficiency of the sward, or grass-plant, left standing for that purpose. In the first of these cases, Mr. Blakie directs a paring-plough to be used; but if that cannot be conveniently obtained, a common plough, with the coulter and share made very sharp, will answer the purpose: a wheel plough is preferable, adds Sinclair, to a swing plough for paring turfs, because it goes steadier, and cuts the turf more regularly. The turf should be cut about 2

5. The grasses best adapted for pasture during the winter.—In the fourth volume of the Trans. of the High Soc. p. 31, is an essay on this subject by the late Mr. George Sinclair. The following are the grasses he recommends as being productive of the most considerable quantity of winter’s grass; and the proportion of seeds which he advises to be sown to produce such a pasture—

<table>
<thead>

Woolly soft-grass (Holcus lanatus), only in cases of considerable elevation and poverty of soil.

Pacey’s perennial rye-grass (Lolium perenne) | 3 pecks |
| Burnet (Potentilla sagittata) | 2 |
| Cow-grass, or perennial red clover (Trifolium pratense) | 6 lbs. |
| White clover (Trifolium repens) | 8 |

The quantity of the grass seeds employed per acre, for permanent ordinary pasture necessarily varies with the nature of the soil. A practical English farmer gives the following as an excellent mixture. (Mark Lane Exp. April 5, 1841.)
GRASS.

inches thick, and 7, 8, or 9 inches wide, according to the nature of the turf-gage of the plough, and the width of the wing of the share; it is sometimes cross cut into short lengths, previous to the operation of paring; but this can only be effected when the turf is moist and free from stones. The cross cutting is done by a scarifier, with cimeter tines, the convex edges made very sharp, and faced to the work, and the implement heavily weighted, so as to press the tines a proper depth into the turf; but it is best in large areas. The turf is then carried in broad-wheeled carts to the field, at the rate of 50 cart-loads to an acre, placed in heaps, and then chopped into small pieces of about 3 inches square; the ground is then levelled with a scarifier, and the turf spread with shovels over the field; the pieces of turf are then placed or planted by women and children, and pressed into the soil by the foot or a wooden rammer. One acre of turf divided into pieces will plant 9 acres—rich pieces—turf, levelled, or rough, rammed, or left as it is. The expense per acre of this mode of converting arable land into pasture is as follows:—

<table>
<thead>

Or 2l. 2s. 9d. per acre. 17 6 4

A plan of improving old worn-out pasture lands (by digging peas and vetches, with a mixture of 18 pounds of Dutch clover, and 2 bushes per acre of Bay grass) is described by Mr. Salter, *Conn. to Board of Agr.* vol. vi. p. 357. On the advantages of deep ploughing, following, and liming land intended to be again laid down to permanent pasture, with an experiment on 17 acres at Jedburgh, there is a paper by Mr. Bell, *Quart. Journ. of Agr.* vol. i. p. 570, and another by Mr. Sinclair (ibid. p. 65). To this gentleman's excellent work (Hort. Gram. Wob.), I would especially commend my readers, as it abounds with information on the grasses. There is also a paper on the economic improvement of grass lands in Scotland (Quart. Journ. of Agr. vol. vii. p. 547); and in all improvements of this kind, the use of the sub-turf plough should not be forgotten by the farmer. See IRRIGATION.

In addition to the original article in the English edition, we deem the subject of grasses so important, and the knowledge of the subject so limited in the United States, that we subjoin the following information derived from the best British authorities.

English writers have divided hay grasses, according to their duration, into two classes—the temporary and permanent. The tall hay grasses of temporary duration, regarded as most valuable, are—

**GRASS.**

Anna or permanent, see Plate of Tall Hay Grasses, Pl. 5, a; Cod's-foot or Orchard Grass (*Dactylis glomerata*), b; and Woolly Soft-Grass (*Holcus lanatus*), c.

Where a crop of hay is desired within the year, it is necessary to resort to such grasses as are annuals in the strict sense of the word; and none (says Loudon) can be better for this purpose than the common oat (*Avena sativa*), cut and made into hay when it comes into flower. Next in order may be mentioned the other cereal grasses, and the annual varieties of *Bromus*; the latter, however, are very coarse grasses, though prolific in culm.

The biennial rye-grass, a variety of the perennial *Lolium*, is almost universally sown in England, either with or without clover, among grain crops, with a view to one crop of hay in the succeeding season. It attains a greater height, and produces a longer, broader spike of flowers than the perennial rye-grass, and the produce in hay is considered greater than that for other oilseed crops, and palatable to cattle. It prefers a rich, loamy soil, but will grow on any surface whatever, except un decayed rock or bog. The perennial rye-grass, which will be more fully described hereafter, differs from the biennial variety in being of somewhat smaller growth, and in continuing in the ground for several years; according to the circumstances of soil and culture. The *Cod's foot* Grass, or, as it is generally called, in the United States, Orchard-Grass, *from* its thriving well in moist shady places, and especially orchards (Pl. 5, b), is an imperfect perennial, and grows naturally on dry, sandy soils. This grass may be recognised by its coarse appearance, both of the leaf and spike, and also by its whitish green hue. It grows freely in most situations, is very hardy and productive, but rough, harsh, and coarse, and much improved by cultivation in open grounds. Hence its name of rugged foot's.

Hay Grasses

Hay Grasses adapted to particular soils & situations

Plate 5
GRASS.

the land meanwhile becoming richer in two or three years from the sheep manure. After midsummer, however, sheep prefer the rye-grass. Sinclair, it is stated, considers "no grass so well suited for all purposes as cock's-foot." (Code of Agriculture.)

It is observed, by high authority, "that if one species only is thought preferable to another in the lucerne husbandry, that species is the cock's-foot, from its more numerous merits. But a certain supply of the most nutritious herbage throughout the season will be in vain looked for from any one species of grass, and can only be found where nature has provided it in a combination of many." (Hort. Gram. Wob., 2d ed. p. 414.)

The Wooley Soft Grass (Pl. 5, c), is an imperfect perennial, and rather a late flowering grass, of a short, unsubstantial appearance, and found chiefly in poor, dry soils. It is, however, a very common grass on all soils, from the richest to the poorest. It affords abundance of seed, light, and easily dispersed by the wind. According to Sinclair, of Woburn, it appears to be generally disliked by all sorts of cattle. It answers, however, for sheep pasture. Being left almost untouched by cattle, it appears the most productive part of the herbage, which leads to a false conception of its produce. The hay made from it is generally disliked by cattle. The Woburn experiments lead to the conclusion that the Holcus mollis, or couch grass, is a better plant for hay than the species here noticed, but that is a more durable perennial, and therefore belongs to another class of grasses.

TALL HAY GRASSES of permanent duration. — "No permanent grass," says Loudon, "has been found equal to the rye-grass for the purposes of convertible husbandry, but others have been selected, which are considered superior for hay meadows. The principal of these are the fescue, fox-tail, and meadow-grass." (Encyc. of Agr.)

Of the various species of fescue grass, there are three held in the highest estimation in England as meadow hay-grasses, viz.: The Meadow or Fertile Fescue Grass (Festuca pratensis, Pl. 5, ad). This is found in rich meadows and pastures, and is highly grateful to all kinds of stock. In England it is more in demand for laying down meadows than any other species, except the rye-grass. The loss sustained by leaving the crop of this grass till the seed be ripe is very great, since by the Woburn experiments it appears that the value of this grass, at the time the seed is ripe, is, to that at the time of flowering, as 6 to 18. It may be observed, that there is a great difference between straws or leaves that have been dried after they were cut in a succulent state, and those which are dried by nature while growing. The former retain all their nutritive powers, but the latter, if completely dry, very little, if any.

The Tall or Infertile Fescue Grass (Festuca elatior, Pl. 5, c). This, in appearance, differs but little from the meadow fescue, except in being larger in every respect. The produce, however, is nearly three times greater; the nutritive properties being also greater, in the proportion of 6 to 8. This grass takes its name in England from its seeds being infertile when cultivated, it being produced by parting the roots and planting them out.

The Spiked Fescue Grass, or Darnel Fescue Grass (Festuca loliacea, Pl. 5, f), resembles the rye-grass in appearance, and the tall fescue in its value as a pasture plant. Sinclair, of Woburn, "considered superior to rye-grass either for hay or permanent pasture, and improves in proportion to its age, which is the reverse of what takes place with the rye-grass."

The Meadow Fox-tail Grass (Alopecurus pratensis, Pl. 5, g), is found in most English meadows, and where the soil is neither very moist nor very dry, but in good heart, is very productive. It also does well on water meadows. Sheep and horses seem to relish it better than oxen. In the Woburn experiments, the result gave nearly three-fourths of produce greater from a clayey loam than from a sandy soil, the grass from the latter being comparatively of less value in the proportion of 4 to 6.

Of the Meadow Grasses, there are two species most esteemed in England and Scotland as hay plants, the smooth-stalked and roughish, which compose the greater part of some of the most celebrated meadows, especially those near Edinburgh.

The Great or Smooth-stalked Meadow Grass—the Spear-grass of America (Festuca pratensis, Pl. 5, h), is distinguished by its height, smooth stem, and creeping roots. According to Sole, it is the best of all the grasses. Its foliage begins to shoot and put on a fine verdure early in the spring, but not so soon as some other grasses. Every animal that eats grass is fond of it; while it makes the best hay, and affords the richest pasture. It abounds in some of the best meadows in Great Britain, and has the valuable property of abiding in the same land, while most other grasses are continually changing. According to some, it delights in rather a dry than a moist soil and situation, on which account it keeps its verdure better in dry seasons, but it thrives most luxuriantly in rich meadows. A loss of more than one-fourth of the value of the whole crop is sustained if it is not cut till the seed be ripe, the straws being then dry, and the root-leaves in a decaying and sickly state. Those of the lattermath, on the contrary, are luxuriant and healthy. This species sends forth flower-stalks but once in a season, and those being the most valuable part of the plant for the purpose of hay, it will, from this circumstance, and the superior value of the grass of the lattermath, compared to that of the seed-crop, appear well adapted for permanent pasture. It was of this grass that the American prize bonnet, in imitation of Leghorn, was manufactured by Miss Woodhouse.

The roughish meadow-grass (Festuca trivialis, Pl. 5, i), delights in moist, rich, and sheltered situations, where it grows 2 feet high, and is very productive. By the Woburn experiments it appears that the proportional value in which the grass of the seed crop exceeds that at the time of flowering is as 8 to 11. The proportional value by which the grass of the lattermath exceeds that of the flowering crop is as 8 to 12, and that of the seed crop as 11 to 12. Here
GRASS.

...is a satisfactory proof of the superior value of the crop at the time the seed is ripe, and of the consequent loss sustained by taking it when in flower; the produce of each crop being nearly equal. The deficiency of hay in the flowering stage in proportion to that of the seed crop is very striking. Its superior produce, the highly nutritious powers which the grass seems to possess, and the season in which it arrives at perfection, are merits which distinguish it as one of the most valuable of those grasses which affect moist, rich soils, and sheltered situations. But on dry, exposed situations, it is altogether inconsiderable; it yearly diminishes, and ultimately dies off, not infrequently in the space of four or five years. (London's Encyclopedia of Agriculture.)

The above constitute six of the best British grasses for either dry or watered meadows. The seeds of the two sorts of meadow-grass are apt to stick together, and when sown with clover and other kinds of seeds, require to be carefully mixed before sowing. The tall and spiky fescue grasses, having a number of barren flowers, are not prolific in seeds, and are therefore seldom to be got at the seedstores, though they may occasionally be had there gathered from plants in that of the seed-grass. As hay grasses, adapted for particular soils and situations, the cat's-tail or timothy, floating fescue, and flaxin grass have been recommended by British agriculturists, though not with perfect unanimity.

The Cat's-tail or Timothy grass (Phleum pratense, Pl. 5, c), is said to be a native of England, although, from its still partial use there, and its universal culture in all the grazing districts of the United States, its valuable properties were here first properly appreciated, as a hay grass taking precedence of all others. It is said to have acquired its name of timothy from its first introducer into Maryland, Timothy Hanson. It is a favourite grass in Sweden, and is destined to become so in England, although some of the highest British authorities upon rural matters, Withering, Swaine, Curtis, and others, have disapproved of its culture, as having no properties in which it is not greatly surpassed by the meadow fescue. Probably some mistakes have been made by the authorities who have treated upon the subject, who have thus referred to different grasses. This is rendered more probable from the fact that the English Flora enumerates six species of cat's-tail, but one of which seems to have any particular claims to the attention of the farmer. The Woburn experiments present timothy as one of the most valuable grasses for hay. In England, according to Donaldson, it has very undeservedly sunk in estimation, as being harsh, late, and yielding little aftermath, and from possessing no quality in which it is superior not to be excelled by the fescue grass. The last observation must have proceeded from a very limited experience, for in general purposes, and in a variety of soils and of climate, it far exceeds the fescue, and also in yielding readily an abundance of sound, healthy seed, while many of the seeds of the fescue are abortive, and the plant is very shy of growth, and confined to the best cultivation.

At the time of flowering, timothy grass produced on one acre 40,837 lbs., when ripe it yielded the same weight, but the quantity of nutritious matter was more than doubled; the lattermuth yielded 9528 lbs., and the same quantity of nutritious matter as at the time of flowering: 1920 grains of leaves gave 80 grains of nutritious matter, and 100 grains of nutritious matter gave 74 of mucilage or starch, 10 of saccharine matter or sugar, and 16 of bitter extractive or saline matter. The ripe crop exceeds the flowerings in value as 14 to 5, which circumstance gives great value to the plant for the purpose of hay. If these statements of comparative produce and value be admitted as an authority, it will be seen that cat's-tail exceeds the fescue grass in every respect except in the produce of the lattermuth: an advantage that is much over-balanced by the greater produce and the ready growth of the timothy grass. It thrives much on peaty lands, and in humid climates, and on all damp soils, and on those that possess a degree of loamy softness in their composition; and is unfit for hot sands, gravels, and chalks, and for hard, sterile clays. With that exception, experience on a great variety of soils and for a long period of time have shown the value of the lattermuth as a pasture grass for general utility. It grows readily and abundantly, yields much seed and of good quality. On very good lands, it has a tendency to produce height of stems in place of number, and the leaves are soon blanched and yellowed with rain in making into hay; but the other grasses have a similar tendency, and they are all inferior to hay grass in producing a crop of the greatest number of stems of an equal height. The time of flowering is little if any later than the cock's-foot, fescue, or ray-grass, and for one crop of hay, or for two and three years' pasture, and for permanent purposes, the meadow cat's-tail must form a very considerable part of the mixture. The comparative merits of this grass will, from the above particulars, appear to be very great; to which may be added, the abundance of fine foliage that it produces early in the spring. In this respect it is only inferior to the narrow-leaved meadow-grass (Poa angustifolia), and Poa fertilis. The value of the straws at the time the seed is ripe exceeds that of the grass at the time of flowering in the proportion of 28 to 10, a circumstance which raises it above many others; for, from this property, its valuable early foliage may be pastured to an advanced period of the season without injury to the crop of hay, a treatment which, in grasses that send forth their flowering straws early in the season, would cause a loss of nearly one half in the value of the crop; and this property of the straws makes the plant peculiarly desirable for hay. Timothy is doubtless a very exhausting crop, and some persons think it entirely too costly a provender for horses in common use, and only to be given to racers, &c. Cock's-foot and rye-grass afford a much cheaper hay, and are not such great exhausters of the soil. It seems certain that for horses no kind of hay is equal to timothy. Mixed with clover it also makes an admirable hay, fit for both horses and cattle. (See Pl. 5, of Tall Hay grasses, a.)
Plate 6

Early Pasture Grasses.

Pasture Grasses adapted to

particular soils and situations.
Grasses, etc. found in Fields and Meadows.
The common Ray or Rye-grass (Lolium perenne), is said to be the first of the grasses cultivated in England, and even in Europe. According to Donaldson, the latest English writer upon grasses, it is still the most prominent, and it has been generally supposed that it was the first plant to be used for pasturage. For several centuries it has been used in England on the original plant, known under the names of Pacey's, Stickney's, and Russell's Ray-grasses, Pacey's and Russell's being considered the best. For more than a century and a half this grass has continued in high repute in England, both for the purpose of a single crop and for pastures, and now constitutes a part of all kinds of the improved mixtures. The modern objection to ray-grass is the shooting up to stems and culms, and the want of foliage, together with a deficiency of aftermarch. "But," says Donaldson, "the first only happens in upland situations and on poor soils, where any other plant would have the same tendency; for on good soils ray-grass grows large, leafy, and succulent, and in many cases it affords as good aftermarch as most others, and forms, when sown with clover, a very useful swale for several years. No plant is liable to greater variation from soil and situation, and hence may have arisen the many discordant opinions of its value; and from being sown singly with clovers it has been more exposed to observation than any other grasses which are usually sown in mixtures, and seldom tried singly for one crop or for a longer duration. It has accordingly been much subjected to fancies and conjectures, which are about equally divided for and against the use of it, the former being yet the most numerous. Coarseness is inferred from the bulky stalks standing uncropped; these might be kept under by early and close grazing, and other grasses are equally objectionable on that point; and it produces stems during the whole season, while some grasses produce only one, and it is not yet known if the leaves or stalks of plants contain most nutriment. So far as our knowledge extends, after all the investigations and best experience upon the subject, ray-grass forms the plant of all others the best suited for general purposes. For a crop of hay along with clovers, no other grass will afford an equal quantity and quality of produce on all the different variety of soils on which they are sown. It yields very readily, and with much less comparative trouble, an abundant sound, healthy seed, and of certain growth; it rises early in the spring, and is much relished by all kinds of stock; the hay is good and fetches a high price, and it is used with much advantage when sown in autumn along with other plants as spring feed for sheep." (Donaldson, on Manures, Grasses, &c.)

After all the experiments that have been made on the other grasses, none, says Louden, have been found to equal the perennial rye-grass for a course of mowing and pasturing for two, three, or seven years. It is sown in Italy, and especially in Lombardy, and also in France and Germany, along with clover, for the same purposes as in England; and, as Von Thaer has remarked, though some have tried other species, both in these countries and in England, they have in the end returned to the rye-grass. When intended as a pasture grass, if stocked hard, and when for hay, if mown early, the objections to it are removed. (Code of Agriculture.)

The Floating Fescue-grass (Festuca fluitans, Pl. 5, I) is found in England in ditches, ponds, and swamps, and in most parts of the country, especially in Cambridgeshire, where it is said to give the peculiar flavour to Cottenham and Cheddar cheese. It is greedily devoured by all kinds of stock, not excepting hogs and ducks, and geese eagerly devour the seeds, which are small, but very sweet and nourishing. They are collected in many parts of Germany and Poland under the name of manna-seeds (schwaeden), and are esteemed a delicacy in soups and gruels. When ground to meal, they make bread very little inferior to that from wheat. Fish feed upon the seeds, and trout are said to thrive greatly in streams where this grass grows abundantly. Curtis justly remarks, that the flote fescue will not flourish except in land that is constantly under water, or converted into a bog or swamp. (London's Ency. of Agr.)

The Water Meadow-grass (Poæ aequatica, Pl. 5, n), is one of the largest of English grasses. It is found chiefly in marshes, but will grow on strong clays, and yield, as the Woburn experiments prove, a prodigious produce. In the fens of Cambridgeshire, Lincolnshire, &c., immense tracts, that used to be overflowed and to produce useless aquatic plants, and which, though drained by mills, still retain much moisture, are covered with this grass, which not only affords rich pasturage in summer, but forms the chief part of the winter fodder. It has a powerfully creeping root, and bears frequent mowing well, sometimes being cut three times in one season. It grows not only in very moist ground, but in the water itself, and with cat-tail, bur-weed, &c., soon fills up ditches, and occasions them to require frequent cleansing. In this respect it is a formidable plant, even in slow rivers. In the Isle of Ely they cleanse these by an instrument called a bear, which is an iron roller, with a number of pieces of iron, like small spades, fixed to it. This is drawn up and down the river by horses walking along the banks, and tears up the plants by the roots, which float and are carried down the stream.

The florin grass (Aegrothis stolonifera, Pl. 5, n), is in England a very common grass, both in wet and dry, rich and poor situations. Few plants, however, appear to be more under the influence of local circumstances than this grass. On dry soils it is worthless, but on rich and moist soils, if we may attach confidence to the accounts given of its produce in Ireland, it is the most valuable of all herbage plants. (See Aegrothis.) Though florin will, in England and Ireland, ripen its seeds on a dry soil, and these seeds being very small, a few pounds
GRASS.

would suffice for an acre, yet it is generally propagated by stolones, or root-shoots. The ground being previously prepared by ploughing, harrowing, and laying into ridges, the shoots are deposited, touching each other at the ends, in drill rows an inch or two deep and about 6 or 9 inches apart. In 6 months, if the planting be performed early in spring, the whole surface will be covered with thick verdure, affording, by autumn, a heavy crop.

With regard to the last described grasses, Mr. Loudon gives it as his opinion, that neither fiorin, timothy, or floating fescue, is ever likely to be cultivated in Britain, though, he observes, they may be cultivated well on the box and moist, rich soils of Ireland, where, to second the influence of the soil, there is a moist warm climate. In regard to the merits of timothy, the reports of several high authorities, one of which (Donaldson) we have just quoted, seem to lead to a very different conclusion. The observation may be strictly applicable to fiorin and floating fescue, both in England and America, although there may be some localities in the United States into which one or other of these may be advantageously introduced.

Pasture Grasses.—In regard to grasses for pasturage, the following selection is given by Loudon, as best adapted to three main purposes; namely:

For early pasture on all soils, the sweet vernal grass (Anthoxanthum odoratum), the sweet-scented soft-grass (Holcus odoratus), the downy oat-grass (Avena pubescens), and the annual meadow-grass (Po<em>a</em> annua).

For late pasture on all soils, the different species of <em>Agrostis</em> and <em>Phleum</em>.

For pasture on poor or secondary soils, the crested dog's-tail (Cynosurus cristatus), hard and sheep's fescue (F. <em>duriuscula</em> and <em>ovina</em>), <em>Po<em>a</em> compressa, cristata</em>, and <em>augustifolia</em>.

The grasses which, according to Loudon, afford most nutritive matter, in early spring, are the foxtail grass and the vernal grass.

The sweet-scented vernal grass (see Pl. 6, a), is common in almost all English pastures, and is that which gives the fragrance to natural or meadow hay. It is chiefly valuable as an early grass; for, though it is culivated by stock, it does not appear to be much relished by them. It is said to thrive best in lands that are deep and moist, and even in peat bogs. Donaldson places it in the lower order of the better grasses. See Anthoxanthum Odoratum.

The downy oat-grass (see Pl. 6, b), according to the Woburn experiments, possesses several good qualities which recommend it to particular notice, as being hardy, early, and more productive than many others which affect similar soils and situations.

The annual meadow-grass (Po<em>a</em> annua, Pl. 6, c), is the most common of all grasses, being the first herbage with which nature covers the earth. The root is annual, and it is almost the only grass that will grow in towns, or near works where the smoke of coal abounds. Though an annual grass, it is found in most meadows and pastures perpetually flowering, and affording an early sweet herbage, relished by all stock, and of as great importance to birds as wheat is to man. It hardly requires to be sown, as it springs up everywhere of itself. However, it may not be amiss to sow a few thousands of it per acre, whenever perpetual pasture (not hay) is the object.

The fine bent (<em>Agrostis vulgaris</em>, see Pl. 6, d), is one of the most common grasses, and one of the earliest. See <em>Agrostis</em> Vulgaris.

The narrow-leaved meadow-grass (Po<em>a</em> augustifolia, see Pl. 6, e), though it flowers late, is remarkable for the early growth of its leaves, which, according to the Woburn experiments, attain to the length of more than 12 inches before the middle of April, and are soft and succulent; in May, however, when the flower-stalks make their appearance, it is subject to the disease termed rust, which affects the whole plant, in consequence of which the produce of the crop is deficient at the time the seeds are ripe. (See <em>Po<em>a</em> Aug<em>ustifolia</em>.) This grass is evidently most valuable for permanent pasture, for which, in consequence of its superior, rapid, and early growth, and the disease beginning at the straws, nature seems to have designed it. The grasses which approach nearest to this in respect to early produce of leaves, are, the fertile meadow-grass, rough cock's-foot, timothy, meadow foxtail, <em>ovina</em> elatior, and <em>bromus</em> <em>littorae</em>, all grasses of a coarser kind.

Late Pasture Grasses.—Of these the principal are timothy, and the various kinds of bent or agrostis. The grasses which are propagated by stolones, like fiorin, and others of the same species, supply pasture throughout the year, the concrete sap laid up in the joints of their roots, rendering them good food even in winter.

Of Pasture grasses for inferior soils, one of the most durable is the dog's-tail grass (Cynosurus cristatus, see Pl. 6, f), in England, a very common grass on dry, clayey or firm surfaces. In the United States it is either little known, or slightly estimated. The foliage is small and rather late in the spring. The wiry stems are refused by cattle, and become very unsightly, and from the smallness of produce, and the dense tufts formed at the roots, it is unfit for alternate husbandry. But for pastures, and for all permanent purposes, if the land be of a dry and hard nature, and inferior in quality, and if sheep are to be fed upon it, this grass must form, according to Donaldson, a principal part of the mixture of seeds sown for that purpose. It is not at all adapted to low swampy situations, but on poor, dry clays, and gravelly soils, it often covers the ground and affords a bite where every other grass had nearly failed.

The hard fescue grass (Festuca duriuscula, see Pl. 6, g), is one of the best of the dwarf sorts of grasses, grateful to all kinds of cattle. It is, in England, present in most good meadows and pastures, and with the sheep's fescue is the best for lawns.

The smooth fescue (F. glabra, see Pl. 6, h), and long-awned sheep's-fescue (F. <em>hordeiformis</em>, Pl. 6, i), greatly resemble the hard fescue, and may be considered equally desirable as pasture and lawn grasses.

The sheep's fescue (F. <em>ovina</em>, Pl. 6, k), is one of the principal pasture grasses for inferior
soils and upland situations, particularly adapted for hilly sheep pastures. It is a low dwarf grass, relished by all kinds of cattle.

The Alpine meadow-grass (Poa alpina, see Pl. 6, l.), tufty hair-grass (Aira cespitosa, Pl. 6, m.), common quaking-grass (Bryza media, Pl. 6, n.), are all dwarf mountain grasses, well adapted for hilly parks or lawns.

GRASSHOPPER (Gryllida). The destructive insects, popularly known in the United States by the name of cockroaches, but which, in our version of the Bible, and in other works in the English language, are called locusts, have, from a period of very high antiquity, attracted the attention of mankind by their extensive and lamentable ravages. It should be remarked, observes Dr. Harris, that in America the name of locust is very improperly given to the cicada of the ancients, or the harvest-fly of English writers. The name of locust will here be restricted to certain kinds of grasshoppers, while the vulgarly named locust, which, according to common belief, appears only once in 17 years, must drop this name and take the more correct one of cicada or harvest-fly. The very frequent misapplication of names, by persons unacquainted with natural history, is one of the greatest obstacles to the progress of science, and shows how necessary it is that things should be called by their right names, if the observations communicated respecting them are to be of any service. Every intelligent farmer is capable of becoming a good observer, and of making valuable discoveries in natural history; but if he be ignorant of the proper names of the objects examined, or if he give to them names, which previously have been applied by other persons to entirely different objects, he will fail to make the result of his observations intelligible and useful to the community.

The insects which Dr. Harris calls locusts, together with other grasshoppers, earwigs, crickets, spectres or walking-sticks, and walking-leaves, soothsayers, cockroaches, are placed under an order called Orthoptera, literally straight-winged; for their wings, when not in use, are folded lengthwise in narrow plates like a fan, and are laid straight along the top or sides of the back. They are also covered by a pair of thicker wing-like members, which, in the locusts and grasshoppers, are long and narrow, and lie lengthwise on the sides of the body, sloping outwards on each side like the roof of a house; in the cockroaches, these upper wings or wing-covers are broader, almost oval, and lie horizontally on the top of the back, overlapping on their inner edges; and in the crickets, the wing-covers, when closed, are placed like those of cockroaches, but have a narrow outer border, which is folded perpendicularly downwards so as to cover the sides of the body also.

The young grasshopper comes from the egg a wingless insect, and consequently unable to move from place to place, in any other way than by the use of its legs; as it grows larger it is soon obliged to cast off its skin, and, after one or two moltings, its body not only increases in size, but becomes proportionally longer than before, while little stump-like wings begin to make their appearance on the top of the back. After this, the grasshopper continues to eat voraciously, grows larger and larger, and hops about without any aid from its short and motionless wings, repeatedly casts off its outgrown skin, appearing each time with still longer wings, and more perfectly formed limbs, till at length it ceases to grow, and, shedding its skin for the last time, it comes forth a perfectly formed and matured grasshopper, with the power of spreading its ample wings, and of using them in flight. (Harris.) See Locusts.

GRATTEN. A term provisionally applied to arable lands in a commonable state. But it is used in Cornwall to imply the mowing of grass the first year after the land has been manured with sea-sand; and this operation they call "mowing in gratten."

GRAUWACKE. A German miner's term, implying gray rock; adopted in geology to designate some of the lowest secondary strata, which form the chief part of the transition rocks of several geologists. See Geology.

GRAVEL. A term applied to a well-known material, consisting of small stones, which vary in size from that of a pea to that of a walnut, or something larger. It is often intermixed with other substances, such as sand, clay, loam, flints, iron ores, &c., from each of which it derives a distinctive appellation. See Geology.

The best kinds of manure for this sort of land are marl, or any stiff clay, cow-dung, chalk, mud, and composts formed of rotten straw from the dung-hill. "Gravels," says Professor Low, in his remarks on soils (El. of Agr. p. 8), "like sands, have all the gradations of quality from fertility to barrenness. The loose soils of this nature, in which the undecomposed material is great, and the intervening soil silicious, are held to be the worst of their kind. These are, in some places, termed 

"Gravels, like sands, are suited to the culture of the different kinds of plants raised for the sake of their roots and tubers; and they are in so peculiar a degree suited to the growth of turnips, that in some parts they receive the distinguishing appellation of turnip soils."

Gravel, if mixed with stiff loam, makes excellent and durable gravel walks for gardens, &c. The kind generally preferred for this purpose, is the red gravel. Previous to laying it down, a solid substratum of lime, rubbish, large flints, or broken earthen pots, or any other hard substance, should be formed to the depth

579
GRAVES.

It will perhaps be generally found that local habit, as being usually the result of experience, is the surest guide. In the opinion, however, of the most intelligent graziers, in stocking enclosures, the cattle should be divided in the following manner:—Supposing our fields, each containing a nearly equal quantity of land, one of them should be kept entirely free from stock until the grass is got up to its full growth, when the prime or fattening cattle should be put into it, that they may get the best of the food; the second best should then follow; and after them either the working or store stock, with lean sheep to eat the pastures close down; thus making the whole of the stock feed over the four enclosures in this succession:—

No. 1. Clear of stock, and reserved for the fattening beasts.
No. 2. For the fattening beasts until sent to No. 1.
No. 3. For the second best cattle, until forwarded successively to Nos. 2 and 1.
No. 4. For stores and sheep to follow the other cattle; then to be shut up until the grass is again ready, as at No. 1, for the fattening beasts.

By this expedient the fattening cattle will pull the choicest parts of the grass, and will advance rapidly toward a state of maturity, for they should always have a full bite of short and sweet grass; and with such cattle, the greatest care should be taken not to overstock the enclosures. It is also advisable to divide the fattening enclosure by hurdles, so as to confine the beasts within half of it at a time, and to allow them the other half at the other, so that they may continually have fresh pasture.

Shade and pure water are essentially necessary; and where there are no trees, rubbing-posts should be set up to prevent the cattle from making that use of the gates and fences. In marsh land, which is chiefly divided by dykes, this, indeed, should never be neglected, as it is materially conducive to their comfort. (Comp. Grazier, 6th edit. p. 74; Brit. Husb. vol. i. p. 482, vol. ii. p. 393; Hillyard’s Farm. and Graz. p. 117.)

GREASE. In farriery, a disease incident to horses or other cattle, consisting of a swelling and inflammation of the legs.

It is sometimes confined to the neighbourhood of the fetlocks; at other times spreading considerably further up the legs, and secreting an oily matter, to which the disease is probably indebted for its name.

It is brought on by sudden changes from a cold to a hot temperature; such as removing horses from grass into hot stables; from hastily substituting a generous after an impoverishing diet; from the negligence of grooms in leaving the heels wet and full of sand; and from constitutional debility.

The farmer’s horse is not so subject to grease as many others, because he is not usually exposed so much to sudden and extreme changes of temperature, and the heels particularly are not thus exposed. In many instances he lives almost entirely out of doors, or, if he is stabled, the stables of the small farmers are not always air-tight. The wind finds its way through many
a cranny, instead of entering at the door alone, and blowing upon the heels. On the first appearance of grease, the heels should be well washed with soap and water, and an ointment of sugar of lead and lard applied. In the more advanced stage, when cracks begin to appear, if they are but slight, a lotion of blue vitriol (sulphate of copper), alum, and water will suffice to dry and close them up; but if they are deep, with an ichorous discharge, and the lameness considerable, it will be necessary to poultice the heel with linseed meal, or carrots boiled soft and mashed. When the inflammation and pain have subsided, the cracks may be dressed with an ointment composed of—resin, 1 part, lard, 3 parts, melted together, and 1 part of camazine afterwards added. (The Horse, p. 277.)

**GREEN MANURES.**

**GREEN CROPS.** Crops, in England, which are consumed on the farm in their unripe state. (See CABBAGES, Tares, Turnips, Carrots, Rotation of Crops, &c.) One of the many great improvements in modern farming, has been the general introduction of green crops, a practice which I think will yet be materially extended; and to this end, for the heavy land farmers, the use of the white or Belgian carrot promises to be very serviceable. Green crops are either fed off, soiled, or ploughed in for manure. (See Green Manures.) When fed off, the fertilizing effects of the sheep pastured upon them are very materially promoted by the addition to their food of oil-cake or of corn, and, as a condiment, common salt. See Clover.

**GREEN FALLOW.** Such land as is rendered clean by means of green crops, without having recourse to naked fallowing. It is a great improvement in modern farming. See Fallowing.

**GREEN FOOD.** Such food as is made use of in its green, succulent state, in the feeding and support of different sorts of live-stock. This kind of food has lately been much more extensively employed than formerly; but its advantages are not, probably, yet so fully understood by farmers in general as they ought. A few plants will, however, show their importance and great utility, when properly made. See Sowling.

**GREEN GRASS (Poa viridis, Poa anna).** A native of the United States, and especially of the Middle and Northern States, where it grows in all meadows and rich soils.—Pl. 6. c. Dr.Muhlenburg says it is not described by Linneus, though nearly allied to his *poa angustifolia*. It may be easily known by the following description: "Culm (or haulm) erect and round (cylindrical), panicle diffuse, spicules five-flowered, and hairy at their base." Cattle are very fond of this grass, if cut when the blossom opens. It produces less than the *Avena elatior*, or tall meadow-oats, but horses prefer it. It continues green until even after frost, and when all other herbage is destroyed; and, if manured, will continue forever. The fine grazing-farm of Mr. William West, of Upper Darby, Delaware county, Pa., consists entirely of this grass. Mr. West finds it necessary to sow clover thinly on the green grass sod every three or four years, to correct a slight tendency which green grass has to bind the soil. When the green grass appears upon meadows made by banking out rivers, care must be taken to secure a supply of water; otherwise, according to Mr. J. Cooper, the ends of the seeds will become affected with a black speck, about one-fourth or one-half an inch in length, similar to the smut on rye, and cause a loss of the hoofs of cattle that eat the grass. (Donacex N. E. Farmer.)

**GREEN-HOUSE.** In gardening, a house with a roof and one or more sides of glass, for the purpose of containing plants in pots which are too tender to endure the open air the greater part of the year. The green-house, being a structure of luxury, ought to be for the most part situated near the house, in order to be enjoyed by the family in inclement weather; and, if possible, it should be connected with the flower-garden, as being of the same character, with reference to use. Its length and breadth may be varied at pleasure, but its height should never be less than that of the loftiest apartment of the house to which it belongs. The best aspect is to the south or south-east; but any aspect may be chosen, provided the roof is entirely of glass, and abundant heat is supplied by art. Of late years, green-house roofs have been made of either cast iron or of zinc, and sometimes in the form of a dome. Both metals are preferable to wood. In green-houses facing to the north, however, the more tender plants will not thrive so well in winter: more artificial heat will be required at that season; and the plants should be chiefly evergreens, and other plants that come into perfection in the cold weather. This is the flower business during winter. In most green-houses the plants are kept in pots or boxes, and set on stages or shelves, in order that they may be near the roof, so as to receive the direct influence of the rays of light, immediately on their passing through the glass. An orangery differs from a green-house in having an opaque roof, and in being chiefly devoted to plants which produce their shoots and flowers in the summer season in the open air; and they are set in the orangery merely to preserve them through the winter. Such a structure is usually but temporary in its turn as a conservatory; but custom in the present day has applied this term to structures having glass roofs, in which the plants are not kept in pots, but planted in the free soil, and in which a part of them are encouraged to grow and flower in the winter months. There are some interesting papers on the subject of green-house plants by Mr. Towers, author of the *Domestic Gardener's Manual*, in the Quart. Journ. of Agr. vol. v. p. 65, vol. vii. p. 48. (Brassicas, &c.) See Conservatory and Orangery.

**GREEN MANURES.** The use of green manures early attracted the attention of the cultivator. Xenophon recommended green
plants to be ploughed into the soil, and even that crops should be raised for that purpose; for these, he says, "enrich the soil as much as dung." And the lupin is named as an excellent manure by very early agricultural writers. The white lupin is even now grown in Italy for the purpose of being ploughed into the soil, an operation generally performed in October.

The buckwheat, which is extensively employed for this purpose in Tuscany, is the leguminous annual plant, well known in our gardens, growing in sandy and loamy soil to the height of two or three feet, with a stem of equal strength with the bean, and having somewhat similar blossoms and pods; but the produce is so bitter, that it is unfit for the nourishment of either man or beast. It arrives to a considerable size in the month of October, when it is ploughed into the soil. It abounds with gluten, which, in fact, its fertilizing effects have been chiefly attributed.

Green manures, although in some measure rendered subservient to the enriching of the soil, as soon as man began to till the earth, and dig in the weeds of his land and the remnants of former crops, have never been systematically employed by the farmer. He has ever been more desirous of employing, as food for his stock, the vegetable produce of his land, than to bury it in the earth to promote the future productiveness of the soil. Yet, whenever green succulent substances, such as weeds, river collections, sea-weed, &c., have been used, the result has always been most satisfactory. The putrefaction of the vegetables, and the gases in that case emitted, appear to be on all occasions highly invigorating and nourishing to the succeeding crop. During this operation, the presence of water is essentially necessary, and is most probably decomposed. The gases produced vary in different plants: those which contain gluten emit ammonia; onions, and a few others, evolve phosphorus; hydrogen, carbonic acid gas, and carburetted hydrogen gas, with various vegetable matters, are almost always abundantly formed. All these gases, when mixed with the soil, are very nourishing to the plants growing upon it. The observations of the farmer assure us that they are so. He tells us that all green manures cannot be employed in too fresh a state; that the best corn is grown where the richest turf has preceded it; and where there is a good produce of red clover, there will assuredly follow an excellent crop of wheat: he finds also, that when he ploughs in his crop of buckwheat to enrich his land, that this is most advantageously done when the plant is coming into flower. The chemical explanation of these practical observations is not difficult. "All green succulent plants," says Davy, "contain saccharine or mucilaginous matter, with woody fibre, and readily ferment; they cannot, therefore, be intended for manure, be used too soon after the white butter. When green crops are to be employed for enriching a soil, they should be ploughed in, if it be possible, when in flower, or at the time the flower is beginning to appear; for it is at this period that they contain the largest quantity of easily soluble substances, and that their leaves are most active in forming nutritive matter. Green crops, pond weeds, the parings of hedges or ditches, or any kind of fresh vegetable matter, require no preparation to fit them for manure. The decomposition slowly proceeds beneath the soil, the soluble matters are gradually dissolved, and the slight fermentation that goes on, checked by the want of a free communication of air, tends to render the woody fibre soluble without occasioning the formation of an injurious liquid matter. When old pastures are broken up and made arable, not only has the soil been enriched by the death and slow decay of the plants which have left soluble matters in the soil, but the roots and leaves of the grasses living at the time, and occupying so large a part of the surface, afford saccharine, mucilaginous, and extractive matters, which become immediately the food of the crop, and the gradual decomposition affords a supply for successive years." (Agr. Chem. p. 280.) Nothing will aid the practical farmer so much in understanding the value of green manure, as a knowledge of the constituent elements of plants. Woody fibre, starch, sugar, gum, are compounds of carbon, hydrogen, and oxygen; the fixed and the volatile oils, wax and resin, are constituted of carbon, with the elements of water, and an excess of hydrogen; vegetable albumen and gluten contain nitrogen as an element; and it is never altogether absent in plants, either in their solid or fluid contents. Now, reflecting upon these facts, it follows that the development of a plant requires the presence of substances containing carbon and nitrogen, and capable of yielding these elements to the growing organism; secondly, of water and its elements; and, lastly, of iron, lime, and other inorganic matters essential to vegetable life. (Eichig's Organic Chem.) It is always refreshing to find the sagacious conclusions of the philosopher supported by the practical farmer's observations. "In October, 1819," said the late Dr. Browne, of Gorstone, in Suffolk, in a letter which he sent to me, "a violent gale of wind drove to this part of the coast an unprecedented quantity of seaweeds. These were eagerly scrambled for; and, from my greater vicinity to the beach, I collected twenty-seven cart-loads, each as much as four horses could draw; and although other persons deposited their collections in their farm-yards, to rot among their other manure, yet I spread mine, fresh and wet, upon little more than an acre of bean stubble, instantly ploughed in, and dibbled wheat upon it. On the 6th of October I then salted the adjoining land with three bushels per acre, manured it with fifteen loads of farm-yard dung per acre, and dibbled it with wheat on the 15th of November. The result was, that the sea-weeded portion gave three times the produce of any equal part of the field." (C. W. Johnson's Essay on Soil, p. 48.)

No one more perseveringly advocated the employment of green manures than the late Mr. Knight. In his paper on the question, he supported his views by some ingenious experiments, and used every argument that could fairly be employed in their favour. "Writers upon agriculture," he observed, "both in ancient and modern times, have dwelt much upon
the advantages of collecting large quantities of vegetable matter to form manures; whilst scarcely any thing has been written upon the state of decomposition in which decaying vegetable substances can be employed most advantageously to afford food to living plants. Both the farmer and gardener, till lately, thought that such manures ought not to be deposited in the soil until putrefaction had nearly destroyed all organic texture, and this opinion is, perhaps, still entertained by the majority of gardeners; it is, however, wholly unfounded. Carnivorous animals, it is well known, receive most nutriment from the flesh of other animals when they obtain it most nearly in the state in which it exists as part of a living body; and the experiments I shall proceed to state, afford evidence of considerable weight that many vegetable substances are best calculated to reanimate an organic living state when they are least changed and decomposed by putrefaction. The allusion to carnivorous animals is misplaced; as green food must be soluble, and in a decomposing state, before it can be taken up by plants; but this does not weaken the argument in favour of its utility. "I had," continues Mr. Knight, "been engaged in the year 1810 in some experiments, from which I hoped to obtain new varieties of the plum, but only one of the blossoms upon which I had operated escaped the severity of the frost in the spring. The seed which this afforded having been preserved in mould during the winter, was in March placed in a small garden pot, which was nearly filled with the living leaves and roots of grasses mixed with a small quantity of earth, and this was sufficiently covered with a layer of mould which contained the roots only of grasses, to prevent, in a great measure, the growth of the plants which were buried. The pot, which contained about one-sixteenth of a square foot of mould and living vegetable matter, was placed under glass, and all about artificial heat, on April 1st. The plant appeared above the soil in the end of April. It was, three times during the summer, removed into a larger pot, and each time supplied with the same matter to feed upon, and in the end of October its roots occupied about the space of one-third of a square foot. Its height above the surface of the mould being then 9 feet 7 inches. In the beginning of June a small piece of ground was planted with potatoes of an early variety, and in some rows green fern, and in others nettles, were employed instead of the mould; and, consequently, as the early potatoes were taken up for use, their tops were buried in rows in the same manner, and potatoes of the preceding year were placed upon them, and buried in the usual way. The days being then long, the ground warm, and the decomposing green leaves and stems affording an abundant moisture, the plants acquired their full growth in an unusually short time, and afforded an abundant produce, and the remaining part of the summer proved more than sufficient to mature potatoes of any early variety. The market gardener may probably employ the tops of his early potatoes and other green vegetable substances in this way with much advantage. "In the preceding experiments the plum stone was placed to vegetate in the turf of the alluvial soil of a meadow, and the potatoes grew in ground in which, though not poor, was not poor, and therefore some objections may be made to the conclusions I am disposed to draw in favour of recent vegetable substances as manures. The following experiment is, I think, decisive. I received from a neighboring farmer a field, naturally barren, and so much exhausted by ill management, that the two preceding crops had not returned a quantity of corn equal to that which had been sown upon it. An adjoining plantation afforded me a large quantity of fern, which I proposed to employ as a manure for a crop of turnips; this was cut between the 10th and 20th of June, but as the small coryledons of the turnip seed afford little to feed the young plant, and as the soil, owing to its extreme poverty, could not afford much nutriment, I thought it necessary to place the fern a few days in a heap to ferment sufficiently to destroy life in it, and to produce an exudation of its juices, and it was then committed in rows to the soil, and the turnip-seed deposited with a drilling machine over it.

"Some adjoining rows were manured with the black vegetable mould obtained from the site of an old wood pile, mixed with the slender branches of trees in every stage of decomposition; the quantity placed in each row appearing to me to exceed more than four times the amount the vegetable mould, if equally decomposed, would have yielded. The crop succeeded in both cases, but the plants upon the green fern grew with more rapidity than the others, and even than those which had been manured with the produce of my fold and stable-yard, and were distinguishable in the autumn from the plants in every other part of the field by the deeper shade of their foliage. I had made, in preceding years, many similar experiments, and found that the very smallest manures (such as those of the mulberry when bearing fruit in pots) with similar results; but I think it unnecessary to trespass on the time of the society by stating these experiments, and conceiving those I have stated to be sufficient to show that any given quantity of vegetable manure can generally be employed in its recent and organized state with much more advantage than when it has been decomposed, and no considerable part of its component parts have been dissipated and lost during the progress of the natural fermentation." (Trans. Hort. Soc. vol. 1. p. 248.)

In an article upon this subject, M. Knoles, of Secheim, writes thus: "My vineyard has been manured for eight years on the branches cut from the vines, without receiving any other manure, and yet more beautiful and richly-laden vines could scarcely be pointed out. The branches are pruned from the vine in August, whilst still fresh and moist, and are traced into the soil after being cut into small pieces. At the end of four weeks not the smallest trace of them can be found."

When green vegetable substances are buried in the soil, they first lose their green colour, speedily wither, and then putrefaction...
soon commences. It is requisite, however, for this purpose, that moisture should be present, and that the temperature of the soil should not be less than about 45°. In this atmosphere has access to the vegetable matter, the putrefaction proceeds with more rapidity, but its presence is not essential. Putrefaction cannot, however, proceed if water is absent, and hence it has been concluded that water is decomposed during the process. The smell which proceeds from the gases emitted varies according to the vegetable substance which is putrefying. Thus, as I have before remarked, those which contain gluten emit ammonia; others, such as the only which evolve phosphoretted hydrogen. All those plants which emit carbonic acid gas and hydrogen gas, which, combined with various vegetable matters, are commonly produced in very copious volumes. When wood decomposes, a portion of oxygen is absorbed from the atmosphere, carbonic acid gas is emitted, and the whole mass is gradually reduced to a dark vegetable mould. This black substance is an excellent fertilizer; plants grow in it with great luxuriance. The soils of some of the famed newly-enclosed American lands owe all their fertility to the abundance of this vegetable mould which they contain. These are the American soils from which we are told 20 successive good crops of wheat have been obtained. There are some lands in the Hundreds of Essex, in Kent, and other places, whose luxuriant, unfailing produce is hardly credible; alternate crops of wheat and beans have been obtained from them from time immemorial. (Johnson on Fermentation, p. 165.) Vegetable mould, as obtained from these places, has been examined by MM. Saussure and Einhoff; by distilling it they obtained from 200 grains (Rec. sur la Veg. p. 162)—

| Carburretted hydrogen | - | - | 124 |
| Carburic acid gas | - | - | 34 |
| Grains | 53 |
| Water containing acetate of ammonia | 10 |
| Emphyreumatic oil | 51 |
| Charcoal | 8 |

By the effects of cultivation, exposure to the action of the atmosphere, and the roots of plants, this mould becomes gradually exhausted in the soil, and the land is of course sensibly impoverished. On this mould the alkali operate very powerfully, almost entirely dissolving it, and hence one great use of soda and potash as fertilizers.

It is also a continued source of carbonic acid, which it emits slowly; hence it might be asserted, that in a good fertile soil there is an atmosphere of carbonic acid, which is the most nutritive food of the young plants raised in it; for when a plant is fully matured, and is fitted to obtain most of its nourishment from the air, the carbonic acid of the soil is no longer required. It is on that account that vegetable mould is so fertile; not by being itself assimilated into the substance of the plant, but by furnishing a slow but lasting supply of carbonic acid.

With regard to the best time to turn under clover, buckwheat, and other green crops, for the purpose of enriching the ground, we have seen in the preceding observations that Davy and others have decided in favour of the period of full vigour, or when the plants may be in blossom. It seems, however, that the results of many well-conducted experiments and repeated observations lead to a different conclusion, namely, that it is best to allow the green crop to decay more or less before ploughing it in. In the course of his agricultural survey of Massachusetts, Mr. Colman found the opinion of some most successful farmers to be in favour of allowing the crop to mature and perish, before it was subjected to the plough as a manure for the soil. As the opinion of such men was at variance with the commonly received one, Mr. Colman addressed a letter to the well-known chemist, Dr. Dana, requesting his views on the matter, as a question for chemical investigation. Dr. Dana’s reply is contained in the report of the commissioner.

The essential element of fertility in a soil, he says, has been called humus, geine, vegetable extract, mould, as well as several other names, all meaning a brownish-black, powdery mass, the result of putrefactive decay, and the remains of decomposed organic matter. This substance combines with the alkaline, earthy, or metallic bases of the plant or the soil, and constitutes the means of growth or nutrition in the new vegetable. Without it, there seems to be no power in the earths of producing vegetation; and if in too great excess, as it sometimes appears to be in very pure manures, it is destructive or unpropitious to all growth. In the question now at issue, the inquiry, of course, was, which furnishes to the soil the greatest quantity of genuine humus, the green or the dried plant. Dr. Dana decides in favour of the later.

Fermentation appears to be the great agent in the decomposition of organic matter; and Dr. Dana’s survey of the several kinds, such as vinous, acetous, and destructive fermentation, seems to have a direct bearing on the formation of the elements of fertility. The juices only that contain sugar or starch, convertible first into gum and then into sugar, by the action of acid vegetable principles, especially gluten, are capable of the vinous fermentation. The conditions necessary to this fermentation are moisture, air, and a temperature not below 50°, nor above 80°.

"If," says Dr. D., "we plough in green plants, we put them in a temperature favourable to the commencement of vinous fermentation; we bury them full of sap, the requisite moisture for vinous fermentation. The sugar and starch of the plant, fermented by its gluten and albumen, are converted into vinegar and alcohol; the former are lost in air, and the last washes away or is changed to vinegar. All that remains for the farmer is the altered gluten and albumen, which soon putrefy and form geine. All the starch and sugar of the plant are thus lost.”

In his remarks on destructive fermentation, Dr. Dana has the following observations:

“Doubtless, all green plants ploughed in undergo, to a greater or less extent, destructive fermentation, which succeeds the vinous and acid fermentations, perhaps caused by the ra-
GREEN MANURES.

pidity of these processes. Hence, in addition to the sugar, gum, and starch of the plant, we lose a large portion of its other substances, by turning it in green. The products of this rapid fermentation have been but little studied. Happily the farmer who never witnesses the process! He should never induce it, and may generally prevent its extension when once begun. It is a dead loss to him; but in all the other cases of putrefaction, the products are valuable."

Will not the remark made above by Dr. D. that the alcohol formed during the vinous fermentation washes away or is converted into vinegar, account for the fact of what some farmers complain of, as souring the soil in turning in heavy crops of green clover? We have heard some very successful farmers and wheat-growers assert that their experience in turning in the clover crop before it had reached maturity, or while abounding in sap, had been so unfavourable, that they had relinquished the practice, and chose either to feed it off with sheep, or let it decay on the ground.

Still, no one can doubt but that excellent effects are produced by turning in green crops, particularly such as buckwheat, of which three or four can be ploughed in a year; thus evidently giving more geine than where the ripened product is turned under. The danger of the practice appears to arise from ploughing in the green crop in that condition, and under such circumstances, that the vinous fermentation and acetous one are so rapid as to convert the valuable products into vinegar, and thus seriously injure the land; or when the destructive fermentation converts the plant into substances unfit for the food or nutrition of vegetables. (Cultivator.)

During the growth of plants, substances containing a large proportion of carbon are excreted or thrown out by the roots, and absorbed by the soil. These substances were either in excess, or unfit for the nutrition of the growing plants. They constituted, therefore, excrementitious matters, through which the soil received again, with usury, the carbon which it had first yielded to the young plants as food, in the form of carboneic acid.

"The soluble matter thus acquired," says Liebig, "by the soil is still capable of decay and putrefaction, and by undergoing these processes furnishes renewed sources of nutrition to another generation of plants; it becomes humus. The cultivated soil is thus placed in a situation exactly analogous to that of forests and woodlands. They constituted, therefore, excrementitious matters, through which the soil received again, with usury, the carbon which it had first yielded to the young plants as food, in the form of carboneic acid."

"Plants do not exhaust the carbon of a soil in the normal or regular condition of their growth; on the contrary, they add to its quantity. But if it is true that plants give back more carbon to a soil than they take from it, it is evident that their growth depends upon the reception of nourishment from the atmosphere in the form of carbonic acid.

"Humus does not nourish plants by being taken up and assimilated in its unaltered state, but by presenting a slow and lasting source of carbonic acid, which is absorbed by the roots, and is the principal nutriment of young plants at a time when, being destitute of leaves, they are unable to extract food from the atmosphere."

The supply of humus usually effected by turning under clover, rye, buckwheat, &c., is accomplished, as Liebig informs us, with much greater certainty when the fields are planted with sainfoin or lucern, a plan now universally adopted in Bingen and its vicinity, the Palatinate, and other parts of Germany, where the fields, thus treated, receive manure only once every nine years. In the first year after the land has been manured, turnips are sown upon it; in the next following years barley, with sainfoin or lucern; in the 7th year, potatoes; in the 8th, wheat; in the 9th, barley; on the 10th year it is again manured, and the same rotation ensues. Sainfoin and lucern are remarkable for the ramifications of their roots and the strong development of their leaves, as well as for requiring but a comparatively small quantity of inorganic matter.

"An immediate consequence of the production of the green principle of the leaves, and of their remaining component parts, as well as those of the stem, is," says Liebig, "the equally abundant excretion of organic matters into the soil from the roots.

"The favorable influence which these exercises on the land, by furnishing it with matter capable of being converted into humus, lasts for several years, but barren spots gradually appear after the lapse of some time. Now it is evident that, after from 6 to 7 years, the ground must become so impregnated with excrements that every fibre of the root will be surrounded with them. As they remain for some time in a soluble condition, the plants must absorb part of them and suffer injurious effects in consequence, because they are not capable of assimilation. When such a field is observed for several years, it is seen that the barren spots are again covered with vegetation (the same plants being always supposed to be grown), while new spots become bare and apparently unfruitful, and so on alternately. The causes which produce this alternate barrenness and fertility in the different parts of the land are evident. The excrements upon the barren spots receiving no new addition, and being subjected to the influence of air and moisture, they pass into putrefaction, and their injurious properties are thus lost to the plants. We now find those substances which formerly prevented their growth removed, and in their place meet with humus, that is, vegetable matter in the act of decay.

"We can scarcely suppose a better means of producing humus than by the growth of plants, the leaves of which are food for animals; for they prepare the soil for plants of every other kind, but particularly for those to which, as to rape and flax, the presence of humus is the most essential condition of growth.

"The reasons why this interchange of crop is so advantageous—the principles which regulate this part of agriculture, are, therefore, the
artificial production of humus, and the cultivation of different kinds of plants upon the same field in such an order of succession, that each shall extract only certain components of the soil, while it leaves behind or restores those which a second or third species of plant may require for its growth and perfect development.

"Now, although the quantity of humus in a soil may be increased to a certain degree by an artificial cultivation, still, in spite of this, there cannot be the smallest doubt that a soil must gradually lose those of its constituents which are removed in the seeds, roots, and leaves of the plants raised upon it. The fertility of soil cannot be restored to a soil, unless we replace it in all those substances of which it has been thus deprived. (Org. Chem.)"

GREEN SAND. This mineral fertilizer, which, in some portions of the United States, has been of so much importance as a manure, and especially in restoring worn-out soils to productivity, is found in great abundance in certain portions of the Atlantic States. The stratum in which it abounds as the principal ingredient commences in Monmouth county, New Jersey, at the base of the Highlands of Newseinek, and along the shore of the Atlantic from the little north of Long Branch to Shark Inlet. Ranging southwestward, it passes in a wide belt through Monmouth, and gradually contracting, runs parallel with the Delaware river, at a distance of a few miles, to Salem. It is prolonged across the state of Delaware, in a narrow strip, to the edge of Maryland, where it disappears under the overlapping tertiary formations. The mineral shows itself again on the Potomac and through the tide-water region of Virginia, but in a different stratum, in which it forms a less proportion than in the so-called "green marl" of New Jersey and Delaware.

The green sand or "marl" of New Jersey, is the second stratum in the ascending order of the five which compose the upper secondary or cretaceous group of that state. Strictly speaking, says Professor H. D. Rogers, it comprises several subordinate beds, all belonging, however, to two principal varieties. In the first of these, the green, granular marl, is the predominant and characteristic ingredient. The second consists, on the other hand, of a dark-blue clay, mingled with more or less silicious sand. This latter material constitutes the usual floor upon which the true green sand deposit rests. In New Jersey, between Long Branch and Deal, the marl stratum has been penetrated thirty feet. The upper two feet consist of a green clay, seemingly derived from the disintegration of the green granules, intermixed with a large proportion of yellowish-white sand. The main marl-bed, having a thickness of about twenty-six feet, contains several subordinate layers; but all contain a large share of the green granules. Beneath the whole there is a grayish-yellow clay, in which the grains abound; they are remarkably large, and are associated with numerous casts of shells.

"When," says Professor Rogers, "we behold a luxuriant harvest, gathered from fields in which the original soil is a kind least of all congenial to vegetation; when we find that all this fertility, contrasting so strikingly with the barrenness around it, proceeds from a few granules of a substance sparsely distributed through the enormous and counteracting expanse of sea-beach sand, more arid than the soil to which it is applied, and we are not led to look with admiration on the potent properties of this curiously constituted mineral! The developments of geology are full of instances like this, showing in how many unlooked-for ways the mineral world may be made subservient to the good of mankind.

"This striking proof of the fertilizing power of the marl ought to encourage those districts not directly within the tract, where some of the conditions in a proper sense of the green granules in a sensible proportion. It expands most materially the limits of the territory where marling may be attempted, and points us to many beds as fertilizing, which otherwise would be deemed wholly inefficacious.

"There can be no doubt that the agriculture of our seaboard states is destined to derive essential benefit from the remarkably wide distribution of this green granular mineral under various geological relationships, besides those in which it presents itself in New Jersey.

"Thus the tertiary shell-marls of Delaware, Maryland, and Virginia, and, I might add, of other states still farther south, contain not unfrequently as high a per centage of the green sand as does the sea-beach sand upon the coast of Monmouth county, New Jersey; and I may mention that my brother, Professor William B. Rogers, of the University of Virginia, charged with the geological survey of that state, has already done important service to the agriculture of some districts, by showing and calling attention to the existence of the green sand in the tertiary strata of Virginia."

"Composition of the green sand. — The predominant and often the sole ingredient in this bed, is a peculiar mineral, occurring always in the form of small, dark granules, about the size of grains of gunpowder. Their form is roundish, and they are often composed of two or three smaller ones united together; a distinctive feature, by which they may at once be recognised from other dark kinds of sand. Though they contain a large portion of nearly fifty per cent. of silica, they are not gritty, but may be readily bruised between the teeth, or upon the nail; and some varieties, when moistened, admit of being kneaded into a half-elastic mass, like impure clay. The prevailing colour of the grains is a deep green, though sometimes the tint is as light as that of verditer. It is often of a dull greenish-blue, and not unfrequently of a dark chocolate colour.

"Along the eastern side of the marl tract in Monmouth, Burlington, and Gloucester, the stratum comprises very generally two varieties of the green sand, distinct as to colour, and holding generally the same relative position to each other. The uppermost layer, where it appears (for it is not always present), is of a light and glowing green, having very nearly the hue of the green paint called verditer; while the lower one is the common dark variety, of a dull bluish-green, or sometimes of a dull blue colour from adhering clay.
GREEN SAND.

"In some instances, particularly where the material constitutes the soil, the granules possess a brownish colour, the consequence evidently of the protoxide of iron which they contain having undergone upon the surface a change to the condition of the peroxide. The dull colour so usual to the surfaces of these grains, when contrasted with the brighter green within the mass, would appear manifestly to proceed from the same cause. Some shade of green may be pronounced to be the colour essential to this mineral, as all the deviations from this tint are attributable either to oxidation or to a thin coating of clay, which frequently encrusts each grain, and from which the deposit is rarely altogether free. When a mass of the green sand or 'marl' is washed, especially with water to which a small quantity of an acid has been added, we invariably find the granules assuming a bright green surface. This colour is also produced in all cases when we mash or bruise a grain, no matter what may be its colour externally. By crushing the grains upon a sheet of white paper, we have an easy and unerring test in the colour of the streak, by which to recognise this material from all other varieties of sand.

"Though the green granular mineral here described constitutes the essential and distinctive ingredient in the green sand stratum, it rarely exists unassociated with several extraneous substances, particularly clay and white silicious sand. These constitute sometimes as large a proportion as fifty per cent. of the bed, causing much variety in its external aspect, and influencing materially its properties as an agricultural agent; the sand, which is generally white or semi-transparent quartz, existing usually in relatively small amount, the clayey matter being ordinarily the most abundant. This latter is of several tints, but is commonly of a light gray or lead colour. It is also occasionally chocolate coloured, brown, and even nearly white. Coating frequently the surfaces of the green grains, it conceals their true colour, imparting its own hue to the entire mass. As it is somewhat adherent when moist, it gives to the stratum where it is abundant the character of a partially plastic clay. Besides the white sand and this clayey material, we often find a minute quantity of finely divided mica mingled with the green sand." (Report of Geological Survey of New Jersey.)

Professor Rogers gives several analyses of specimens of green sand obtained from pits in various parts of the region where this mineral abounds near the surface of the ground. In some of the beds the green sand is mixed with proportions of clay and common quartzose sand, while in others, although ten per cent. of clay may be present, no common sand is perceptible. Besides the clay and common sand usually present with the green sand in the general mass, there occur occasionally several other substances, "which, though comparatively minute in quantity, are," observes Professor Rogers, "possessed of active properties. Some of these materials are probably deleterious, while others are undoubtedly beneficial in their action upon vegetation. The substances referred to are carbonate of lime, sulphate of iron (coppersas), sulphate of alumina, sulphate of lime, and sulphate of magnesia; also phosphate of iron.

"They appear to be derived, mainly, at least, from constituents in the clay, and only very partially, if at all, from elements in the green sand itself."

"The carbonate of lime, in most instances, we can trace to fossil shells and other organic remains, imbedded in the stratum. The sulphate of iron obviously proceeds from the action of the atmosphere and moisture on the sulphuret of iron, so abundant in the clay; and the sulphate of alumina from the union of a portion of the sulphuric acid thus developed with the argillaceous earth of the clay; while the sulphates of lime and magnesia may result, either from the combination of the same acid with some of the lime and magnesia, sometimes present in a minute share in the green mineral, or, more probably, from its reaction on the carbonates of lime and magnesia, existing, like the sulphuret of iron, in an insulated state. The phosphate of iron is no doubt derived from phosphoric acid, traceable to the animal remains, acting on oxide of iron.

"Several of these substances develop themselves upon the mass of the marl after it has been dug and exposed to the atmosphere, in the form of a white efflorescence, encrusting alike the clayey matter and the granules of green sand with a delicate crystallization, resembling a light frost. Collected and carefully examined and analyzed, this efflorescence will be found almost invariably to consist, when it is of a pure white, of either the sulphate of magnesia or sulphate of lime (gypsum), the latter predominating; and sometimes these two occur united. In some instances, we recognise it to contain the sulphate of magnesia (Epsom salts) in sufficient quantity to be distinguishable by its taste. A yellowish tint and an astrangent flavour are apparent when it consists chiefly of the sulphates of alumina and iron. The carbonate of lime more generally shows itself, not in the shape of an efflorescence on the surface, like the others, but dispersed in minute granules throughout the body of the marl. Many of these calcareous granules are grains of dolomite, analogous in composition to the marl. Many of these calcareous granules are grains of dolomite, analogous in composition to the magnesian variety of the limestone, which overlies the green sand; whence, probably, the true source of the sulphate of magnesia above referred to. When the traces of shells are very numerous in the bed, and their conversion into the sulphate of lime has happened on the large scale, the gypsum forms a conspicuous part of a soft, white, clayey matter, derived from the shells and interspersed among the green grains. The mixed mass of carbonate and sulphate of lime is then usually in a yellowish-white, chalky condition. Sometimes we may detect the gypsum in the marl in the shape of small regular crystals of transparent selenite, at times so minute as only to be detected by the microscope.

"Various fossil shells, and other marine organic remains, amounting to considerably more than one hundred species, are scattered through the green sand. These collections of fossils would seem to be most abundant in those parts"
of the stratum which consist largely of the green sand.

"The water, percolating through the overlying sands, and also through the pervious green sand itself, has effected, and is daily effecting, important changes in the condition of the shells and other fossils; sometimes replacing their carbonate of lime with oxide of iron, sometimes removing it altogether, and leaving a mere mould, forming either an inner or an outer cast, and sometimes obliterating nearly every trace of their former presence.

"The total thickness of the green sand formation, being estimated from the bottom of the lowermost layers abounding in the green granular mineral to the overlying yellow ferruginous sands, or the limestone bed, when this is present, may be stated approximately at about one hundred feet. The only place in the whole district where it is practicable to ascertain, with any approach to accuracy, either the depth of the formation, or the relative situation and number of the separate beds which it comprises, is along the shore of Sandy Hook bay, in the cliffs of the Newerksink highlands. This, the only coast section of the strata, is still an imperfect one; large masses of the upper beds, fallen from above, covering the lower deposits near the water-side.

"Owing to the large amount of water which it usually contains, the green sand is rarely penetrated in the numerous diggings which are made in it for the marl, to a greater depth than about twenty feet, the pits becoming at that limit too wet to be prosecuted deeper.

"In one or two instances, wells have been sunk through the stratum, and the depth of the green sand ascertained to be about thirty feet, as already mentioned.

"Specific Gravity.—The specific gravity of the green granular mineral, carefully freed from all extraneous adhering matter, is, according to several experiments cautiously made, about 2-65. Three different specimens, taken from remote localities, gave for the two lowest each 2-63; for the highest, 2-70.

"The hardness of this mineral varies materially, being dependent somewhat upon the time elapsed after it has been dug: it is softest when moist and recently uncovered. Freshly extracted, its hardness often does not exceed that of tale; but when long uncovered and dry, it nearly equals that of gypsum.

"It would appear by experiment to be entirely insoluble in water, both cold and boiling; but it dissolves with tolerable facility in any of the stronger acids, though different specimens vary materially in this respect."

The experience of farmers, continued through nearly half a century, had amply tested the utility of green sand as an active fertilizer when spread upon the ground. Various were the views maintained in regard to its active principles, and much speculation was, as usual, indulged upon the subject. The demonstration, made first by Mr. Henry Seybert, of Philadelphia, that the green sand of New Jersey contained a considerable amount of potash, seemed to afford a very satisfactory clue by which its mysterious effects might be traced out.

588

"Chemical composition of Green Sand. From a number of analysis of specimens of this mineral, selected with the greatest care by Professor Rogers, and ascertained to be entirely free from extraneous matter, it would seem that it is not quite uniform in its composition, but exhibits slight variations in the proportions of its principal constituents. The following results will serve to display the prevailing chemical nature of green sand, and the moderate variation of the several ingredients:

Green Sand of Squankum.

Description.—Colour, a dark olive-green; granules of a medium size; it composes 58-36 per cent. of the marl of the upper part of the bed, and 72-36 per cent. of the lower.

Composition.—In 100 parts:

Comparing the details of the several analyses furnished by Professor Rogers, we perceive that the green sand, even when of the greatest purity, is not absolutely constant, either in the nature of the ingredients which enter into its composition, or in their relative proportions. The per centage of the silica varies from 47.5 to 51.5; that of the alumina from 6 to 9.35; that of the protoxide of iron from 20.86 to 24.74; that of the potash from 9.36 to 12.96; and that of the water from 5.5 to 9.5. We find, moreover, that, in some instances, besides these elements, lime enters into the constitution of the green sand, in other cases magnesia; while, occasionally, both occur. The amount of these earths is, however, always inconsiderable.

It appears that the mean proportion of the silica is approximately 49.5 per cent.; that of the alumina 7.5; of the protoxide of iron 22.8; of the potash 11.5; and of the water 7.9 per
GREEN SAND.

cent.; while the lime, when present, seldom exceeds one-half per cent, and the magnesia is rarely more than a mere trace.

A comparison of the green sand of New Jersey with that of France, shows no essential difference in their chemical nature.

The absence of potash in the green granules of the English green sand, and the large proportion of magnesia, are facts not a little remarkable.

Economical relations of the Green Sand formation.—Abundant evidence might be adduced to prove that the true fertilizing principle in marl is not lime, but potash. The analyses which have been made give us, in several cases, no lime at all; and where a small proportion of lime is present in the green granular mineral, it is in a combined state, chemically united with the other ingredients, and not traceable to the organic remains which are in many of these instances not present in the stratum. Besides, the quantity of shelly matter, even where the shells are plentiful, is so disproportionately small, and the matter of the shells often so fine and unsusceptible of that easy disintegration necessary to form a calcareous marl adapted to act speedily upon the crop, that the striking effects witnessed from the marl can in nowise be attributed to the trivial amount of lime which the shells may occasionally furnish to the land. Nevertheless, as some feebly beneficial effects may possibly arise from this source, it may be of service to the agriculturist in choosing between different fossiliferous marls, to attend to the nature of the particular fossils, and the state of more or less decomposition or change in which they are to be found.

Selection of Green Sand.—For judging of the quality of a marl by observation, says Professor Rogers, "some familiarity with the multiform aspects which it assumes is indispensable. The leading rule, however, is to bear in mind that the fertilizing efficacy of the compound resides in the minute, round, greenish grains which compose most, or sometimes all of it; and that it seems, moreover, to be dependent upon the proportion in these green grains of those powerful alkaline stimulants to vegetation, potash and lime, but specially potash. The first thing, then, is to approximate to the relative quantity of the green grains in the whole mass, and this may be effected with a greater or less degree of accuracy in several ways. The simplest and readiest method is to employ a small pocket magnifying glass, and to become familiar with the dark green grains, so as to distinguish them at once from other dark varieties of sand which sometimes occur associated with them. A little practice will very soon enable one to use the glass expertly, and to arrive at a pretty true estimate of the probable percentage of the green granules. But as these granules cannot sometimes be distinguished from the grains of ordinary white flinty sand, or from other kinds, in consequence of the particles being all alike coated with a thin film of the dark cementing clay, it will be useful to adopt some method of bringing out, under the magnifier, their different characteristics of colour and form. Let the mass be washed in a large glass tumbler, and repeatedly agitated with the water, until as much of the clay as possible has been detached from the grains. After pouring off the turbid water by repeated rinsings, and permitting it to settle until clear, we may estimate the comparative quantity of clay in different marls by the relative amount of sediment which subsides. If we wish to be more accurate, we can weigh out a given quantity of the marl, then pursue the above plan, and decant the clear water from the clay, and after thoroughly drying the clay, weigh it to ascertain its zonal. Having got away most of the clay, we should spread out the granular matter upon a sheet of paper and dry it, when there will be no further difficulty in distinguishing, by their colour and lustre, the foreign impurities from the grains of true marl, and also of estimating the relative abundance of each. When the marl to be examined contains much clay, I would recommend the experiments to be made upon a regularly weighed quantity, weighing both the clayey and the granular portions. A delicate apothecary's balance will commonly be found accurate enough. Another more expeditious, though less accurate method, is merely to dry the marl, spread it extremely thin upon a sheet of white paper, and then hold it near a window, or in the light, to examine it carefully by the magnifier. The flinty sand, though stained with clay, may then be clearly discerned in consequence of its transparency; whereas, when we inspect a solid lump, all the particles upon the surface are nearly alike dark.

"A useful suggestion is, to place a portion of the marl upon a hot stove, or on the top of a store, when all the granules will change from their ordinary green tint to a light red or brick colour, while the other materials of the mass sustain little alteration. This will often render obvious to the naked eye the proportion of the green grains.

"When there is a yellowish or whitish incrustation upon the marl after the moist surface has remained for some time exposed to the weather, it is indicative of the existence of a portion of either copperas or sulphate of alumina, the hurtful nature of which has already been explained.

"An astringent inky taste will very often de
Green Sand.

Professor Hitchcock, in his Elementary Geology, has given the following tabular view of the analysis of specimens of green sand from different countries:

Application and effect of Green Sand.—The resemblance in composition of green sand to glass, each being composed mainly of silice and potash, is striking. The investigations of Liebig demonstrated the indispensable importance to the growth of many plants, and especially to wheat, of silice and potash in that state of commixture called by chemists silicate of potash. He even went so far as to declare an opinion that one of the best of manures that could be applied to the wheat crop would be a solution of glass. In making this admirable induction, he was, apparently, unaware of the fact that a natural kind of glass, or silicate of potash, under the form of green sand, had been long spread over the American fields with the most striking advantages to the growth of wheat and other crops.

The effects of green sand applied as a manure, are strongly set forth in the following extracts from Professor H. D. Rogers’s Report of his Geological Survey of New Jersey:

"Mr. Woolley manured pieces of land in the proportion of 20 loads of good stable manure to the acre, applying upon an adjacent tract of the same soil his marl in the ratio of about 20 loads per acre. The crops, which were timothy and clover, were much heavier upon the section which had received the marl; and there was this additional fact greatly in favour of the fossil manure over the putrescent one, that the soil was also entirely free from weeds, while the stable manure had rendered its own crop very foul."

"This green sand stratum at Poplar Swamp seems to be almost entirely free from any sulphate of iron or other astringent material, and as a consequence the crops seem not to be scorched by an extra dose, however lavishly applied."

"There can be no doubt that 20 loads of marl per acre must be regarded as an unnecessarily bountiful dressing; but computing the relative cost of the two manures, when employed in the ratio above stated, we find a
GREEN SAND.

considerable disparity in favour of the green sand. Placing the home value of farm-yard manure at 100 cents for each two-horse load, and that of the marl at 25 cents per load, we have the expense of manuring one acre $500; or forking the same $5.

"This being an experiment, an extravagantly large dressing of manure was employed, but not exceeding the usual average application more than the 20 loads of marl surpassed what was necessary.

"Experience has already shown that land once amply manured retains its fertility with little diminution for at least 10 or 12 years, if care be had not to crop it too severely; while with all practicable precaution the stable manure must be renewed at least three times in that interval to maintain in the soil a corresponding degree of vigour.

"At the Squankum pits, which are very extensive, the marl is sold at the rate of 37½ cents the load, the purchasers having to dig it. It is transported by wagons to a distance, in some directions, of 20 miles, and retailed, when hauled that far, at the rate of 10, or even 12½ cents per bushel, being very profitably spread upon the soil in the small proportion of 25 or even 20 bushels to the acre.

This is certainly a strong proof of the high estimation in which green sand is held as a manure by the prudent and thrifty farmers of New Jersey.

Professor Booth, in the report of his geological survey of the state of Delaware, has given much highly interesting information in regard to green sand. In all essential particulars, the marl-beds found in Newcastle county resemble those of New Jersey described by Professor Rogers.

"Practically speaking," says Prof. Booth, "there are two principal kinds of green sand, that containing lime as an essential ingredient, and that consisting chiefly of green particles. The former contains variable quantities of carbonate of lime, the highest limit yet observed being twenty-five per cent. The average composition of the latter, in its natural state and selected, may be thus expressed:

</table>

The first is either cretaceous, containing finely divided carbonate of lime not formed by comminuted shells, and occurring on the canal; or decomposed calcareous, on the western limit of the state, from which the calcareous matter has been wholly or partially removed, although abounding in casts of shells; or shelly green sand, on the southern line of St. George's hundred, in which there is no fine calcareous matter but that of comminuted shells. The second contains mere traces of lime, and consists of green sand particles, with variable quantities of clay and common sand, and is either bluish-green, and of the finest quality, as found on Drawyer's and Silver Run; or yellowish-green, containing white siliceous sand, as on Draw-

er's and the Appoquinimink; or black-coloured, decomposed externally, rarely internally, and containing both white sand and argillaceous matter, from Silver Run to Scott's Run; or dark-coloured, containing pyrites, as from the south-west corner of St. George's hundred, and along the ridge to the Deep-cut; or, lastly, the blue micaceous sand of the Deep-cut, rarely containing particles of green sand, although abounding with casts and impressions of shells characteristic of the green sand formation. We have seen that the yellow sand is the principal member of the series, both over and underlying the green sand; that it is characterized by its uniformity of grain and colour, and, rising to the surface, constitutes the chief and most valuable soil of the region. We farther observe that the green sand stratum is undulating, and varies in its depth, the average thickness being 21 feet, from which we may form a rough estimate of the amount contained in the whole district. It is 7 miles long, and nearly 6½ broad, and therefore embraces about 44 square miles. Deducting from this one-quarter for the place where it fines out, and for streams, ravines, &c., we have 33 square miles underlaid by green sand. There are then 105,920,000 square yards, which multiplied by 7 yards, the average thickness, gives 715,545,600 cubic yards of green sand in Delaware. Supposing, then, that the 1-100th part of it is accessible, we have more than 7,000,000 cubic yards which may be made available. In a majority of cases, the flowing of water into the pits presents a source of inconvenience that may be remedied without great difficulty, and with a trifling expense, compared with the value of the material.

Upon the subject of the fertilizing properties of green sand, Professor Booth makes the following highly interesting observations:

"When it is decomposed by the ordinary processes of the laboratory, only a small quantity of silica and all the other constituents being dissolved, we may regard the oxide of iron, potassa, and alumina as performing the principal functions, assisted by the presence of water. The useful action of potash or of ashes in the soil has been long acknowledged, and hence, as soon as it was known that the green sand contained potassa, its utility was immediately referred to that alkali; latterly, however, the opinion has gained ground that the protoxide of iron plays an important part by acting with the organic matter in the soil, in a manner resembling the saponification of oil by potash.

"The addition of much unheated ashes to a soil determines the formation of salts of potassa, which, being very soluble, are taken up in excess by growing plants, and produce such luxuriant vegetation as to cause it, technically speaking, to burn up. The same operation would probably occur with protoxide of iron, were its salts not soon converted into more insoluble humate and crenate of the peroxtide.

"It might be objected by many that green sand being decomposed with difficulty by the powerful acids of the laboratory, there is little probability that it can be resolved into its constituents by the feeble action of humic or at-
mospheric agents. Independently, however, of the proof of its decomposition by its induc-
ing increased fertility, and of the mode by
which nature, operating with feeble agents
during a lengthened period of time, produces
great results, it may be shown that it is more
readily decomposed than is generally admitted.
William M. Uhler, in conjunction with the
author of this memoir, has lately been engaged
in making a series of experiments on this sub-
ject, which, although incomplete, nevertheless
afford sufficient grounds for drawing a few
conclusions. Dilute acetic acid decomposed
green sand after the lapse of a week or more;
oxalic acid produced the same result in a few
days, and in the course of two weeks nearly
all the green sand had disappeared, and the
yellow oxalate of iron precipitated. But the
most surprising effects were produced by the
action of carbonic acid, one of the feeblest
known to the chemist, the use of which for this
purpose was first proposed by Mr. Charles Ro-
berts, of Philadelphia. By a well-charged so-
lution of this acid a large portion of the sand
was decomposed in a few days, and a weak
solution induced the same effects in the course
in a few weeks. Although few experiments
were made to determine quantitatively the re-
lation amounts of the constituents taken up by
the acids, yet the qualitative tests were suffi-
cient to show that all the ingredients were se-
parated from each other, and that the green sand
might be analyzed even by the feeble
operation of carbonic acid.

"As the present state of our knowledge of
these subjects is limited when compared with
that advanced stage which we firmly believe
chemistry will produce in process of time, it
would be presumption to make unhesitating
assertions relative to the modus operandi of
organic and inorganic manures; we may, ne-
evertheless, and indeed we ought to draw such
inferences as are consistent with our present
knowledge of facts. The potassa of the green
sand appears to act on organic matter in the
soil by catalysis forming soluble salts of po-
tassa; the protoxide of iron acts in a similar
manner, but is itself changed to a less soluble
compound; and the alumina probably has a
similar action, proportional to its feeble affini-
ty. To the question that, since potassa acts in
this manner, why does not a large quantity of
green sand produce excessive luxuriance? it
may be answered, that it does where the quan-
tity is very large, but that its action is modified
and its effects are largely by the difficulty with which the
marl is decomposed, and by the presence of
other bases besides potassa. When green sand
is decomposed by nature or in the laboratory,
a small quantity of silica is taken up, and even
this substance, by forming a salt with erenic
acid, may assist in increasing fertility, as it is an
essential constituent of plants.

"There are two points touching the theory
of the operation of green sand, which remain
to be noticed, the first of which is, that when
its decomposition has commenced, it advances in
an increasing ratio; and the second, that
the constituents of green sand in their nascent
state, that is, at the moment of their disengage-
ment from the compound, act with much
greater energy. Thus it would appear, then,
that all the constituents of the marl exercise
an influence in promoting vegetation and this
action must take place in proportion to their
respective affinities, potassa being the most
powerful, followed by lime, magnesia, protox-
ide of iron, alumina, and silica; that the first
four assist in the generation of organic acids,
with which they and a small portion of alumina
and silica combine to form salts of different
degrees, but generally of difficult solubility,
which non-fish and invigorate nascent vegeta-
tion; that by the presence of bases of such a
nature, a more prolonged and healthy action is
insured.

"The above remarks relative to the mode
of operation of marl, apply equally to the sev-
eral varieties, as far as relates to the content of
green grains, but the calcareous species owe
their action partly to lime, in proportion as its
carbonate exists in the marl. When phosphate
of iron occurs in quantity, some notice must
be taken of its probable influence, for regard-
to it, we can only reason from theory, since it
has never been applied directly to land, with
the view of ascertaining its effects on vegeta-
tion. It appears from the analyses of Berthier,
that both phosphate of lime and of iron exist
in appreciable quantity in the ashes of plants;
for, in the composition of oak ashes, he divides
the 7 per cent. of phosphoric acid between lime
and iron in such a manner as to form
nearly 14 per cent. of phosphate of lime, and
l per cent. of phosphate of iron; and in other
cases he gives the amount of the salt of iron
as high as 9 per cent.; and we believe from
experience that the utility of bone manure is
largely due to its phosphate of lime; and hence
we may infer that the marl alluded to may be
serviceable, or even very valuable, from its
phosphate of iron; and that if it were mingled
with a little lime, where it is wanting in the
marl, the atmospheric and humic agents, if the
expression be allowed, will cause such a trans-
mutation of the constituents as to bring both
phosphates to exert their influence in advanc-
ing the growth of plants. It would appear un-
necessary to add lime, when there is already
a small quantity in the marl, were it not that
there is still another substance mentioned as
occurring chiefly in the marl of the dividing
ridge and deep cut. This substance is the
sulphuret of iron, the presence of which is
shown by the large amount of white efflores-
cence with which it becomes coated after ex-
posure to the air, precisely similar to those pits
where it is observed in pieces of considerable
size. After the marl has been exposed to the
air for a short time, a whitish efflorescence
forms on its surface, which has a strong styp-
tic taste, and is the sulphate of iron, formed
from the sulphuret; but the snow-white efflo-
rescence is chiefly sulphate of lime, or plaster.
Now, the latter marl contains lime, and the
former does not; and hence this operation of
nature in the formation of plaster from sulphu-
ret of iron points out to us the manner of at-
taining the same result, viz., by mixing with
marl which exhibits an efflorescence after ex-
posure to the air, a quantity of lime sufficient
of marl will be shown to be striking on ordinary, and even on very poor land, yet it is essential that the soil should contain a fair proportion of organic matter, in order to reap the highest benefit from it. Hence the failure of some experiments made with the green sand; for, although it stands superior to lime for requiring the presence or addition of less organic manure, still the views offered to explain its mode of action show the necessity of some organic materials on which to operate, and this conclusion is strengthened by experience.

"The difficulty of overcoming prejudice is clearly exemplified in the progressive employment of green sand in Delaware. One of the first experiments made with it in St. George's hundred may probably be dated as far back as the year 1836, when a small quantity was drawn out from the site of the canal. One spot of ground where this was applied was observed in 1837 on the farm of James Wilson, eleven years after its application; and although that soil had received no other assistance, a luxuriant growth of corn clearly pointed out the limit to which it had been spread."

The cost of the green sand marl at the pits, where these beds lie near the surface, is comparatively trifling, so that it can be raised and hauled to the distance of a mile or two for three cents per bushel, and yield a small profit. Its weight is very great, owing principally to the large proportion of iron contained. Reference to its specific gravity (2.63—2.70), as determined by Professor Rogers, shows it to be nearly three times heavier than the same bulk of a measure of water, a bushel weighing from 110 to 120 lbs. This, of course, causes its transportation to be expensive, except where facilities for water carriage are at hand. For fields worn out by long culture, the green sand is generally found of immediate and permanent advantage. Under such circumstances every successive crop having removed from the soil a portion of the potash which existed in abundance in the first years of its culture, the absence of this essential agent of fertility has been supplied by the green sand. Where ashes have been formerly applied freely, it is needless to expect much apparent benefit, and the same may be said where the soil is already duly supplied with potash from the decomposition of feldspar, or mica, all of which contain proportions of potash which they contribute to the soil. Hence the source of frequent failures in deriving advantage from the application of green sand.

GREYHOUND. This is one of the principal coursing agents, being a dog remarkable for his swiftness, strength, and sagacity, in pursuing game.

There are several varieties, such as the Italian, the Oriental, and the Highland greyhound; the last of which is now become exceedingly scarce. A good greyhound ought to have a long and rather large body, a neat pointed head, sparkling eyes, a long mouth with sharp teeth, small ears, formed of a thin cartilage; a broad and strong chest; his fore legs straight and short, his hind legs long and limber; broad shoulders, round ribs, muscular buttocks, but not fat, and a long tail, strong and full of sp
GRIP.

news. (Treatise on Greyhounds.) As it is out of our province, in a work of this nature, to treat at large of coursing and its agents, we must refer the sportsman who wishes for detailed information on the points of a good greyhound, and on breeding, feeding, &c., to that excellent manual of reference for all matters relating to the chase, Blaine’s Encyclopaedia of Rural Sports, a very learned and carefully arranged work, digested and compiled by a master hand.

GRAVES. A small gutter, or ditch, cut across a field, to drain it. When cut for draining, it is mostly called a water or draining furrow.

A good method of draining meadow or swarland, by drips, is that of cutting out the pieces in a somewhat wedge-like form, taking off the bottom part, and then replacing them, by which means, a hollow is left below, for permitting the water to flow off.

Grip is also provincially used to signify the hollow or cavity behind the cattle, in cow-houses or cattle-sheds, into which the dung and urine is discharged. These cavities should always be sunk about 8, 10, or 12 inches below the surface on which the cattle stand.

GRIPES, or COLIC. We have found that, in the absence of a veterinary surgeon in this dangerous complaint, the following is the best remedy for a horse:—4 lb. of linseed oil, 1 ½ quarts of warm water. Some persons assist the operation of the above with a glyster composed of ½ lb. of epsom salts, ½ lb. of treacle, dissolved in three quarts of warm water. See CATTLE, and SHEEP, Diseases of.

GRIT. Hard sandstone, employed for mill-stones and grindstones, pavement, &c.

GRITS. See GROATS.

GROATS. In agriculture, are the small grains formed from oats after having the husks or shells taken off the grain. When crushed, they are called Embden groats. Gruel made from groats is a mild, little nutritive, easily digested food, well adapted for cases of fever and inflammation. An ounce of groats should make a quart of gruel; the mixture should be cooked slowly, with a little butter while boiling; and when cold, the clear liquor poured off from the sediment. Sugar or lemon juice may be added if circumstances admit of such additions.

GROMWELL; GRAY MILLET (Lithospermum, from lithos a stone, and sperma a seed. The little nuts or seeds being extremely hard, and having a surface as smooth as a polished pebble). Of this herbaceous perennial plant there are four indigenous species in England.

1. The common gromwell (L. officinale), grommill, gray-mill, or gray millet, for it has various local names, which grows in dry, gravelly, or chalky soils, and frequently among rubbish and ruins, blowing pale buff flowers, in May and June. The root is tapering, strong, and whitish. The whole herb rough with minute, close, callous bristles. The stem is annual, nearly two feet high, branched and leafy. The leaves are sessile, alternate, grayish-green, ovate or lanceolate. The seeds are gray, with a kind of porcelain polish, and a stony hardness; when new, they have been falsely reported to contain calcareous earths, effervescing with acids.

These seeds afford excellent flour, which might in times of scarcity be converted into bread.

2. Corn gromwell. See BASTARD CANTER.

3. Creeping or purple gromwell (L. purpureum). A rare plant, found occasionally in thickets on a chalky soil.

4. Sea gromwell (L. maritimum), growing in many parts of the coast of Scotland and the north of England on the sea-shore among sand or loose stones. The whole herb is remarkable for its beautiful glaucous hue. (Eng. Flor. vol. i. p. 254.)

The field lithospernum, or stoneweed, a worthless plant, is the only species described by Dr. Darlington, as found in Pennsylvania. There are five or six additional species in the United States. (Flora Cestrina.)

GROOM (Flem. grom, a boy). A name now usually applied to servants who are employed about horses. The chief requisites in a groom are, a mild disposition, and a fondness for the animals of which he has the care. Great attention is also necessary to the feeding, dressing, littering, and cleaning of the horses. Each of these different operations should be daily executed with regularity and exactness. The stable, as well as the various articles that belong to it, should also always be kept clean and in perfect order.

GROUND CHERRY (Physalis viscosa), clumby viscosa. The specific name of this American plant is derived from the Greek word Physa, a bladder or bag, in allusion to its inflated calyx, or seed-pod. It is found in fields, fence-rows, &c., where, in the Middle States, it flowers in July. The root is annual, the stem growing 12 to 18 inches high, with spreading branches. Leaves 2 to 4 inches long, and 3 to 6 inches wide, roundish ovate or oblong. Flower greenish-yellow, with purplish-brown spots at the base. The berry succeeding the flower is roundish, viscid, enclosed in the inflated calyx, and of a greenish-yellow colour, and when fully mature, orange. The flower stems are very hairy. The ripe berries of one of the more hairy varieties of the ground cherry (P. Pennsylvanica), are orange-coloured, more succulent than some others, and rather palatable. (Flora Cestrina.)

GROUND IVY. See ALEHOOF.

GROUND-NUT (Apios tuberosa. From apios a pear, in allusion to its pear-shaped tubers) sometimes called wild bean. An American plant, growing in the Middle States, having a perennial root, producing oval tubers half an inch or more in diameter at the base of the stem. The stem is from 4 to 8 feet long, slender, striate, slightly hairy, sparingly branched, and climbing. The flower blooms in August, is of a dingy purple with tinges of green, rather handsome and pleasantly fragrant. The tubers on the roots are esculent and nutritious, and the plant has been considered an object worthy of culture. It is the only species of the genus. (Flora Cestrina.)

Another plant producing a ground nut is the Arachis hypogea. This is an annual plant, with long, trailing stalks. A native of Mexico, but now cultivated in the West Indies for its nuts, which are oblong, and grow beneath the surface. These are used by the negroes as food. But in France they are now cultivated for the
abundance of the oil they produce. This is said to be equally as valuable, for the table and other purposes, as the oil of olives, and superior to that for burning. A bushel of the nuts produces by cold expression a gallon of oil; but more may be produced by heat, but of a quality inferior. (Am. Orchideat.)

**GUANO.**

An extensive genus of plants, many of the species of which are very ornamental. Of this genus Sir John Smith includes ten species as indigenous to England, four only of which, however, come properly under the head groundsel. The remainder are referred to under the name of Ragwort, by which name they are generally known.

Common groundsel, or Sisson (S. vulgaris), grows almost everywhere in cultivated and waste grounds, in rubbish, dry banks, the tops of walls, &c.; it flowers almost all the year. It is too well known to need description. Cage birds (particularly goldfinches and linnets) are fed with the young buds, seeds, and leaves, which are cooling, and have a saltish herbageous flavour. Cows do not relish this plant; it is, however, eaten by goats and swine, but refused by horses and sheep. A weak infusion of groundsel is in England a common purge; a strong infusion or juice is used as an emetic, and sometimes given to horses to free them from bots. All the groundseeds are annual.

Fifteen or sixteen species of senecio are found in the United States, of which Dr. Dur-lington met with four in Pennsylvania. These are:—1. The golden; 2. The obovate, which in New York is called squaw-weed, and denounced as poisons to sheep. 3. Balsamita-like, common groundsel. 4. Fireweed, or hie-racium-leaved. This plant is remarkable for its prevalence in newly cleared grounds, especially around spots where bushwood has been burned; whence it derives its name of fire-weed.

**GRUB.** The common name for worms or maggots extracted from the eggs of beetles. Under the name of gentle grub are a principal bait to the angler for many kinds of fish. The grub produces the beetle, and is by some called the rook-worm, because rooks are particularly fond of it. Land newly brought into cultivation is generally most subject to the grub. The best way of destroying it is by good and frequent ploughings, and the applications of lime in pretty large proportions in its caustic or most active state, or common salt. Irrigation is also very beneficial, as tending to destroy the grub. See Beeltes and Insects.

**GRUBBER, or CULTIVATOR.** See Har-row and Scarifier.

**GUANO.** The name of a manure recently imported for the first time into England, which has long been extensively employed by the cultivators of Peru to fertilize their sterile sandy places—lands, on which occasionally there is a total absence of rain for many months. This manure is the excrements of sea-birds, and, like that produced by all animals feeding on animal food, is of a very powerful description. According to M. Humboldt, in the greatest abundance is found on the small rocky islands of the Pacific Ocean, as at Chinchoe, Ilo, Iza, and Arica. Even when Humboldt wrote, some 20 years since, 50 ves- sels were annually loaded with the guano at Chinchoe alone, each trader carrying from 1500 to 2000 cubic feet. The guano is found on the surface of these islands, in strata of several feet in thickness, and is, in fact, the putrefying excrements of innumerable sea-fowl that remain on them during the breeding season. It is used by the farmers of Peru chiefly as a manure for the maize or Indian corn, and is said sometimes in the small proportion of about 1 cwt. per acre. "The date of the discovery of the guano and of its introduction as a manure," says Mr. Winterfield, "is unknown, although no doubt exists of its great antiquity. In many parts of America, where the soil is volcanic or sandy, no produce would be obtained without the guano. It has been calculated that from 12,000 to 14,000 cwt. are annually sold in the port of Mollendo for the use of the country round the city of Arequipa. In the province of Taracapa and in the valleys of Tambo and Victor the consumption should be something more, as wheat, all kinds of fruit, trees and plants, with the single exception of the sugarcane, are manured with the guano; which is not the case with the district of Are-quipa, where maize and the potato alone re-quire it. In the district of Arequipa 3 cwt. of guano is spread over an extent of 5000 square yards (about an English acre); but in Taracapa and the valleys of Tambo and Victor, 5 cwt. are required. The land thus manured in Arequipa produces 45 for 1 of potatoes, and 35 for 1 of maize, where wheat manured with horse dung produces only 18.''

There are, it seems, three varieties of guano, which bear on the coast of Peru different prices. "The white guano is considered the most valuable, as being fresher and purer. It is found on nearly all the islands along the coast. The red and dark gray are worth 2s. 3d. the cwt.; a higher price is given for the white guano on account of its greater scarcity; it is sold at the port of Mollendo at 3s. 6d. per cwt., and at times, during the war, it has obtained as high a price as 12s."

It appears, in the state in which it has been lately introduced into England, to be a fine brown or fawn-coloured powder, emitting a strong marine smell: it blackens when heated, and gives off strong ammoniacal fumes. When nitric acid is mixed with it, uric or lithic acid is produced. It has been analyzed by various chemists. In 1806, an analysis of a very ela-borate description was published by MM. Fourcroy and Vanquelin; they found in it a part of its weight of uric acid, partly saturated with ammonia and partly with potash. Some phos- phate of lime and ammonia, and small quanti-ties of sulphate and muriate of potash, a little fatty matter, and a portion of sand. It has been more recently analyzed by Mr. Hennell of Apo-thecaries' Hall, who found in guano——

</tbody>
</table>

In a few words, it may be regarded as a compound of urate of ammonia and other salts. There is no doubt that it is a very powerful manure; the very composition of its salts would indicate this fact. Thus, uric or lithic acid, which is a fine white powder, nearly insoluble in water (17:20 parts of water only dissolving 1 part of uric acid), is composed, according to Dr. Prout (Thompson's Chem. vol. ii. p. 187), of—

Urate of ammonia and urate of potash are fine white powders, also very insoluble in water: of the phosphate of lime, of the guano, the earthy salt, and most valuable portions of bones, it is unnecessary to comment; I have, in my work "On the Fertilizers, p. 136," endeavoured to show how essentially valuable this salt is to all the farmer's commonly cultivated crops. The use of the dung of birds is not a modern improvement, for that of poultry has been adopted as a manure from a very early period. M. P. Cato, the earliest of the agricultural writers, in his work, (lib. lxxvii.) commends the use of pigeons' dung for meadows, corn-lands, or gardens. And John Worlidge, in 1669, was warm in the praise of the dung of fowls. "Pigeons' or hens' dung," he says (Myst. of Agri. 71), "is incomparable: one load is worth ten loads of other dung, and is therefore usually sown on wheat or barley that lieth far off and is not easy to be helped." And he says, in another place, "A flock of wild geese had pitched upon a parcel of green wheat, and had eaten it up clean, and sat thereon, and dunged it several nights; that the owner despaired of having any crop that year; but the contrary happened, for he had a far richer stock of wheat there than any of his neighbours had." In some experiments made by Mr. Skirving of Walton, near Liverpool, in 1841, the guano was tried at the rate of two or three cwts. per acre, as a manure for Swedish turnips and Italian rye-grass, with very considerable success; it appeared to be equally, or rather more, efficacious than 20 cubic yards per acre of farm-yard manure. The most elaborate set of experiments upon the guano with which I am acquainted were made, in 1810, for potatoes and mangel-wurzel, at the island of St. Helena, by the late General Beaton; and they are the more valuable from being comparative. The soil on which these experiments were made was rather stiff, being composed of blackish mould, intermixed with friable fat clay. The following table gives the results of every experiment: 35 loads of horse-dung litter per acre were used, 33 of hogs' dung litter, and 33 bushes per acre of the guano.

The guano, or sea-fowl dung, adds General Beatson, which is found in considerable quantities upon Ege Island, was first recommended to my notice by Sir Joseph Banks, President of the Royal Society. “It furnishes,” says he, “the loading of an immense number of vessels that are constantly employed in bringing it from small islands to the main land on the west coast of South America, where it is sold and distributed for the purpose of manure, for which it answers in a degree infinitely superior to any other article we have the knowledge of. A handful is considered as sufficient for several square yards of land, the produce of which is exuberant in consequence of the force of this application.”

The accuracy of this valuable communication has been most amply confirmed by my experiments in the culture of potatoes, as well as upon grass lands. Thirty-five bushels of the guano, or 3 cart loads per acre appear to be equivalent in effect to 70 loads of good rotten dung. I should imagine that abundance of this most valuable manure might be had from many of the rocks and islands on the coast of Scotland. The effect of the guano upon grass lands is comparatively greater than in the potato experiment. From what cause this proceeds it may be difficult to explain; but as Dr. Priestley found, by experiment, that vegetables thrive best when they were made to grow in air made purified by the decomposition of animal and vegetable substances, it may be inferred that the very strong effluvia which issue from the sea-fowl dung or guano, together with its being readily washed among the roots of vegetables by the first falls of rain, are circumstances that may possibly render its effects as a top-dressing greatly superior to those it produces when it is mixed with the soil. On the 29th of July, 1808, I marked out a space on the lawn in front of Plantation House, which measured 1 rod in breadth and 12 rods in length; this was divided into 12 equal parts, or square rods, and numbered progressively from 1 to 12. The guano was reduced to a powder and sifted, and upon No. 1 a quart of this powder was evenly strewn by the hand; this is at the rate of 5 Winchester bushels per acre, because 160 square rods, or an acre, would have required that number of quarts, or exactly 5 bushels. In the same manner No. 2 had 2 quarts, No. 3, 3 quarts, and so on to No. 12, which had 12 quarts, or at the rate of 60 bushels per acre. From the 29th of July there were daily drizzling rains until the 5th of August, when the effect of this invaluable manure began to appear. On the following day the whole extent of the 12 rods became highly verdant, and exhibited such a contrast to the unmanured part of the lawn, that it had the appearance of having been newly turfed with a finer kind of sod. The effect gradually increased, and in the first week of October, that is, in a little more than two months, the higher numbers, from 6 to 12, having from 30 to 60 bushels per acre, excited the surprise of every person who saw them, being covered with the most exuberant grass that can be imagined, and having more the resemblance of a crop of young wheat very thickly sown, than of any grass I ever beheld. This is more remarkable, as at that time the copious rains which fell in August and the spring season had made no visible effect on the adjoining part of the lawn. It was from a frequent and careful inspection of the above experiments that I have estimated 35 bushels of guano per acre to be equivalent in effect upon grass land to forty bushels of well-rotted dung. I have been informed that guano is sold at Lima, and at other towns on the coast of Peru, for a dollar a bag of 50 pounds weight, and that it is much in use there for manuring fruit trees and gardens. It is certainly one of the most powerful of manures, and therefore it is necessary to be cautious in using it. I have observed, when too much is laid on grass, that it burns and destroys it. I would, therefore, recommend to those who may try it on fruit trees, to begin with not more than three-quarters of a pint to each tree, and to trenched it about a foot deep all round the roots. If the first application be found insufficient, a second or third may be given at intervals of two or three months; or a better mode, perhaps, of determining the quantity of guano proper for each fruit tree, would be to select about a dozen trees of the same kind and size, and to vary the quantities by an easy progression, from three-quarters of a pint to one or two quarts, or more, to each tree. (Comm. Board of Agr., vol. vii. p. 229-249.)

The price at present of guano in England is 25s. per cwt., or £1.2 per ton. As it costs only about 3s. per cwt. at the South American ports, near which it is obtained, it should be imported and sold at a lower price.

In any case, says J. F. W. Johnston, it seems improbable that guano can continue to be imported into England for any length of time. It is absolutely necessary to the cultivation of the land in Peru,—and it is also diminishing in quantity,—the first settled government, therefore, which is formed in that country, must prohibit the further exportation of a substance so important to the national interests. It is a matter not unworthy of the attention of chemists, therefore, to consider whether a mixture similar to the guano, and of equal efficacy, cannot be formed by art—not only at a cost so reasonable as at once to make the farmer independent of the importer, but also in such abundance as at the same time to place so valuable a manure within the reach of all.

Several attempts have been made to manufacture an artificial guano, and the results have shown considerable success.

The following mixture contains the various
ingredients found in guano in nearly the average proportion; and Mr. Johnston believes it is probable to be at least as efficacious as the natural guano, for all the crops to which the latter has hitherto been applied.

The quantity here indicated may be intimately mixed with 100 lbs. of chalk, and will be fully equal in efficacy, I believe, to 4 cwt. of guano, now selling at £5.

Sulphate of ammonia is now manufactured largely at Glasgow, and may be had for less than 20s. a cwt.

In England the guano is entirely a new fertiliser. About 20 casks were imported in 1840 by Mr. Myers, of Liverpool; and in the year 1841 one or two more cargoes arrived from the Pacific. The enterprise which has thus led him to bring so many thousands of miles this long-employed manure of South America, is certainly highly to the credit of an English merchant. That it promises well to agriculture, no one will doubt who attends carefully to its chemical composition; and it is more than probable that by avoiding the application of it in quantities too small, and by the use of the drill, a valuable fertiliser will be added to the manures already in the farmer's possession. But I would warn my agricultural friends not to be led away by idle assertions respecting its powers, such as that a single cwt. is sufficient for an acre of ground; from 2 to 4 cwt. is the smallest quantity that should be applied by the drill. Let them beware, too, of adulterations; the price has already tempted the small dealers to mix it with other substances. Forty thousand tons were imported into England during the year 1842.

From some recent notices of it in the Farmers' Magazine for December, 1841, I find that Mr. Smith, of Gunton Park, Norfolk, applied 200 pounds of guano on the same field, on an equal space of land, 15 bushels of bone dust. Both were drilled into the ground with seed wheat. The bone dust gave 43 quarters of wheat, the guano 6 quarters 2 bushels 14 pecks.

Mr. Love, of Shoreham, Sevenoaks, observes, "I mixed 14 pounds, in the first instance, with 2 bushels of ashes, and although the weather was very dry, I could perceive a marked difference in the growth of the plants a few days after they made their appearance. Encouraged by my success, I then mixed 28 pounds with 15 bushels of ashes, and applied for turnips by sowing broadcast on the land, and harrowing it in lightly. As we had frequent showers at the time, the seed soon vegetated, and the plants grew away from these manured with dung and mould. In each case I applied it at the rate of 2 cwt. to an acre."  

Mr. John Crane Not, of Hollow, Worcestershire, remarks, "I applied it to my hop-grounds, and, in order to give it a fair trial, I put about a pint to every alternate hill in each row. The effect was marvellous; the plants were so luxuriant, while the adjoining ones, not so manured, were sickly and weak."

**GUINEA FOWL.** See FOWLS.
cultivated. About ten years since, it was also introduced into the East Indies, where it is now successfully cultivated, and grows to the height of seven feet: it admits of being frequently cut, and makes excellent hay. Cattle eat it, both in a fresh and dry state, with great avidity: hence the culture of this valuable herbage has been strongly recommended to the farmers of Cornwall and Devonshire.

The following remarks on the culture of this grass are by the late H. Lawrence, of South Carolina.

"In the last spring, I procured from Jamaica three-half pints of Guinea grass seed, which I planted in the drills of one-fourth part of an acre of very indifferent land; the seed sprung up and soon covered the ground with grass four feet high and upwards. Being desirous of saving as much seed as possible, I cut one bundle of grass for horses: they ate it all with great avidity.

"In August I took one of the grass roots and divided it into 28 parts, which were immediately replanted: every part took root, and the whole are now growing very finely and seeding. I am of opinion this grass will make the best pasture we can wish for. From former experience I have reason to believe the Guinea grass is perennial. It is easily managed, requires but one good hoeing, after which it will takes care of itself.

"I am informed a gentleman near Kingston, in Jamaica, makes upwards of 1000l. sterling per annum by Guinea grass hay." (Domestic Encyclopedia.)

GUINEA PIG (Cavia cobaya). This curious little animal is not a native of Guinea, but of Brazil, whence it has been imported into Europe. It is about seven inches in length, and its white body is variegated with irregular black and orange-coloured spots. In their wild state these animals multiply prodigiously, and would become innumerable, if they were capable of sustaining cold and moisture. The female breeds at two months old, and brings forth 10, 12, or 14 young ones, several times in the course of the year, after a gestation of three weeks. Guinea pigs feed on all kinds of herbs, but are particularly fond of parsley, as also of apples and other fruits.

GULLION. A provincial name for gripes in horses. See GRISES.

GUM, BLACK. See BLACK GUM.

GYPSUM. See PLASTER OF PARIS.

H.

HACK, or HACKNEY. In horsemanship, a general term for a road horse, which does not always convey any sense of inferiority, or refer to horses let out for hire. It is, however, often used in that sense.

HACKBERRY. The banks of the Delaware above Philadelphia may be considered as the north-eastern limit of the hackberry. East of the mountains it is restricted within narrow boundaries, and it is a stranger to the lower part of Virginia, and to the more Southern States: I have found it abundant, says Michaux, only on the banks of the Susquehanna and of the Potomac, particularly on the Susquehanna near Columbia and Harrisburg. It is profusely multiplied, on the contrary, in the western country in all the valleys that stretch along the rivers, and wherever the soil is fertile, throughout Kentucky and Tennessee. On the Ohio, from Pittsburgh to Marietta, it is called hoopash, and in Kentucky, hackberry; a name whose origin I am unable to trace.

This is one of the finest trees that compose the dusky forests on this part of the Ohio. It associates with the buttonwood, black walnut, butternut, basswood, black sugar-maple, elm, and sweet locust, which it equals in stature but not in bulk, being sometimes more than 80 feet high, with a disproportionate diameter of 18 or 20 inches.

The hackberry is easily distinguished by the form of its trunk, which is straight and undivided to a great height, and by its bark, which is grayish, unbroken, and covered with asperities unevenly distributed over its surface. Its leaves are larger than those of any other species of nettle tree, being 6 inches long and 3 or 4 inches broad. They are oval-acuminate, denticulated, cordiform at the base, of a thick, substantial texture, and of a rude surface. The flowers are small, white, and often united in pairs on a common peduncle. The fruit is round, about as large as a pea, and black at its maturity. The wood is fine-grained and compact, but not heavy, and when freshly exposed it is perfectly white; when it is exposed to the weather it is frequently rendered translucent by the exudation of a fluid. It is used for the making of boxes.

HACKMATACK, or American larch (Larix Americana). The European and American larches, says Michaux, are more strictly confined than any other resinous trees to the northern
HAIR.

The larch is justly appreciated in the United States, but it is little employed, because it is rare and may be replaced by several resinosum trees which are cheaper and more abundant. Sir A. B. Lambert, in his splendid work upon the pines, describes two species of the American larch, the first of which is evidently the tree we have been considering; the second he denominates _Larix virescens_, and characterizes it by smaller fruit and drooping branches. My father doubtless considered it as a variety, and has omitted to mention it: as I have never visited the northern parts of America, I cannot decide the question.

The cones of the European larch are twice as large as those of the American species, but the two trees are so analogous that a separate description is unnecessary. (Am. Spruce.)

HAIR (Germ. haare). The characteristic covering of the mammiferous class of animals. It consists of slender, more or less elongated, horny filaments, secreted by a matrix, consisting of a conical gland or bulb, and a capsule, which is situated in the meshwork of the corium or true skin. The hairs pass out through canals in the corium, which are lined by a thin layer of cuticle adherent to the base of the hair: the straightness or curl of the hair depends on the form of the glandual thorn found within the bulb. The hair is formed in an elongated sheath or sack, to the bottom of which the bulb or soft part of the hair is fixed. The structure of hairs differs: thus, in the bristle of the hog there is an internal cellular part, and an external or cortical fibrous part; and this is also the structure of the hair of the roe deer. The hair of the bat is knotted, and that of the mouse is mottled with black and white. Hair is usually distinguished into various kinds, according to its size and appearance. The strongest and stiffest of all is called _bristle_: of this kind is the hair on the backs of hogs. When remarkably fine, soft, and pliable, it is called _wool_, and the finest of all is known by the name of _down_. Spines, bristles, fur, and wool (see those heads) are therefore all modifications of hair, having the same chemical composition, mode of formation, and general structure.

In the spine of the porcupine, the bulb secretes a fluted pith, and the capsule invests it with a horny sheath, the transparency of which allows the ridges of the central part to be seen. In the spine-like whiskers of the walrus, as well as the bristles of the hog, the twofold structure of the hair is very conspicuous; but in the finer kind of hair, as of the human head and beard, the central pith can only be demonstrated in fine transverse sections, viewed with a microscope. Some kinds of hair, as of the human head, the mane and tail of the horse, are perennial, and grow continuously by a persisting activity of the formative capsule and pulp: other kinds, as the ordinary hair of the horse, cow, and deer, are annual, and the coat is shed at particular seasons. In the deer the horns are shed contemporaneously with the deciduous hair.

Many quadrupeds, especially those of cold climates, have two kinds of hair: a long and coarse kind, forming their visible external covering; and a shorter, finer, and more
HAIR GRASS. See AIRA.

HALESIA. The name of two beautiful species of shrub, or small trees, natives of North Carolina and other Southern States. They are known by the familiar names of silver-bell and snow-drop tree, and are highly ornamental, producing very early, whilst the tree is completely leafless, a profusion of snow-white hanging blossoms, having a pleasant odour and very much frequented by humming-birds, bees, and other insects. The flowers are disposed in bunches all along the branches, each bud producing from 4 to 8 or 9. The flowering continues during two or three weeks, and the blossoms are succeeded by pretty large winged juiceless drupes, hanging likewise in bunches.

The tree is propagated by cuttings or suckers from the roots, and appear to stand the severe winters of this country very well. A Halesia, with several distinct trunks from the original root, is now flourishing at the seat of J. Cowperthwait, Esq., near Bristol, Pennsylvania. It is quite an old tree, and has attained the height of 35 or 40 feet. There are two species of halesia, one called flower-winged (H. tetraptera), and the other the two-winged (H. dipera). The leaves of the latter are six times the size of the former, and the fruit has two large wings and two minute ones.

HAM (Dutch, hammen; Fr. jambon). In commerce denotes the thigh of a hog or bear salted and dried, so as to preserve it in a state possessing a pungent and agreeable flavour. York, Hams, Wilts, and Cumberland in England, and Dumfries and Galloway in Scotland, are the counties most famous for producing fine hams. Those of Ireland are comparatively coarse, and without flavour. See Bacon. The hams of Portugal, Westphalia, and Virginia are exquisitely flavoured, and are in high estimation. The method of curing hams in the most celebrated districts, is to rub them very hard with bay or other salt; then leave them on a stone bench, in the sun, so that the salt may discharge itself. In a few days the rubbing process is repeated; about half an ounce of salt-petre (nitrate of potassa) being added to each ham. When they have continued about a week longer on the bench, or in the salting-tub, among the brine, they are commonly hung up to dry in the sides of large open chimneys; some have them exposed to the smoke of wood, peats, coals, or other sorts of fuel, while others carefully avoid having them smoked. And when not sold sooner, they are continued in these situations till the approach of warm weather, when they are packed up in casks with straw, or the seeds of oatmeal, and consigned for sale. Hams lose about 20 per cent. of their weight in drying.

Hams may be cured in order to resemble, in taste, those of Westphalia, by the following process:—Cover a young ham of pork with dry salt; let it be for 24 hours to draw off the blood; then wipe it perfectly dry, and take one pound of brown sugar, a quarter of a pound of salt-petre, half a pint of bay salt, and three pints of salt; mix these ingredients in an iron pan over the fire, and stir them continually till they acquire a moderate degree of heat. In this pickle the ham must be suffered to remain for three weeks, frequently turning it, when it should be suspended in a chimney for drying by means of smoke from no other but a wood fire. The smoke from oak saw-dust or shavings is the best for imparting a fine flavour. This smoke contains imperfectly formed pyrogenous acid, which is the agent that communicates the flavour to the Westphalia hams. In Dumfriesshire the pickle for hams is sometimes made with one-half ale, which renders the hams shorter, and adds greatly to the richness of their flavour. The imports of bacon and hams into England, have been kept low by the heavy duty of 28s. exacted on each cwt. But the duty having been recently greatly reduced, a large amount of hams cured in America will be sent to the English market. In 1845, the duty on foreign hams imported into England was reduced to 1s. the cwt., or just half of what it had been for many years. On those imported from British colonies the duty was
HARE (Lepus timidus). The hare is naturally a timid animal, and extremely swift in motion when pursued by dogs. Hares are dispersed over almost every climate, and consequently the varieties are extremely numerous; and the sizes, forms, and habits, adapted to the physical wants of the family, greatly multiplies their diversities. Although hunte in all countries, being prolific in the extreme, their species does not apparently diminish in number. They begin to breed in the first year, and the female generally produces four or five leverets, after a gestation of about 31 or 32 days; and she is supposed to breed four or five times in the year. Unlike dogs, the eyes of these animals are open at their birth; and after being suckled for about three weeks, they are abandoned to their fate. Hares in a state of nature are believed to live from 9 to 12 years. The hare is known to have been a favourite object of the chase more than 2000 years ago.

Two or three species of the hare genus are natives of the United States. The common American rabbit, found all over the country, is the Lepus Americanus and Lepus Hudsonius of naturalists. It is smaller than the English hare, and even less than the European rabbit. In dry places it often burrows in the earth, and is very prolific, bringing forth 3 or 4 times a year from 5 to 10 at a time. It carries its young about 6 weeks. In the domestic state the male rabbit will often destroy the young.

A second American species is the Varying Hare, the Lepus Virginianus or Lepus variabilis of naturalists. This inhabits the Southern and Middle States, and most probably as far north as New England. Its colour is grayish-brown in summer, and white in winter; the orbits of the eyes are at all times surrounded by a reddish fawn-colour; tail very short. The largest of this species are about 18 inches, total length, and weigh from 7 to 8 lbs. These animals never burrow, but frequent meadows, &c, near the base of mountains, and when pursued retreat into hollow trees. They bring forth several times a year, 3 or 4 at a birth, after a gestation of about 30 days.

In the extreme northerly parts of the continent. Captains Parry, Sabine, and other travellers, describe another American species under the name of Lepus glacialis, which is somewhat larger than the varying rabbit, being 2 feet 4 inches from the end of the nose to the arms, the average weight being 8 lbs. The ears are longer in proportion than those of the common hare, and especially those of the varying rabbit. The fur is exceedingly thick and woolly, of the purest white in the spring and autumn, excepting a tuft of long black hair at the tip of the ears, which is reddish-brown at the base. The whiskers are also black at the base for one-half their length. In the summer the back and sides become a little grayish, the fur beneath still remaining white. The lepus glacialis, or hare of the icy regions, inhabits the Arctic circle, Greenland (where it remains continuously during the summer). The food consists chiefly of tender herbs gathered from ravines. (Fauna Americana.)

HARRIFF, Goose-Grass, Cliders, Cleavers, or Catchweed (Galium aparine). Pl. 10, h. This is an annual plant, with a fibrous root, growing in hedges almost everywhere. It is found wild even in Nepal. The flowers are small, pale, and buff-coloured, few together, on lateral leafy stalks, and blowing from May to August. The root is fibrous. The stem branched, brittle, supporting itself upon other plants; often three or four feet long. The leaves are cut into thin, sometimes hooked, which are also abundant on the edges and keels of the leaves, by all which the herb sticks to the hands and clothes of those who touch it, as well as to the coats of animals, as do likewise the seeds. The fruit is a double globe, beset with minute, short hooks. The expressed juice of the herb is reckoned anti-scorbutic; but this is doubtful, as well as some imaginary virtues in cancer which have been attributed to it. The roasted seeds are said to be no bad substitute for coffee, to which they are botanically related.

Three-flowered goose-grass is one of the names of the rough-fruited common bed straw. (G. tricorne).

HARRIERS. A breed of dogs kept principally for hunting the hare. There are three prominent varieties of the harrier,—the old southern hound, the modern harrier, and the beagle. Subordinate divisions occur, and a cross breed is used in hunting the otter. The modern harrier is little more than a fox-hound. The size and form of the harrier, like those of the fox-hound, should be adapted to the nature of the country hunted over. Some sportsmen have a peuchant for packs of under-sized harriers; and a gentleman of the name of Harding used to hunt the open grounds about Dorchester with about 17 couple, which were not more than 16 or 17 inches high. (Blaine's Rural Sports, p. 404.)

HARROW. For the chief portion of the following article, I am indebted to the Messrs. Ransome, the celebrated agricultural implement makers of Ipswich; than whom no persons can be better acquainted with the construction and uses of different machines and implements for agricultural purposes. This instrument succeeds to the plough in the natural order of description, and in the uses to which it is applicable. Its purpose is to pulverize the ground which has been moved by the plough, to disengage from it the weeds and roots which it may contain; or to cover the
Plate 15

Fig 5

HARROWS, EXTIRPATORS and SCARIFIERS.
seeds of the cultivated plants, when sown.
The form of the plough has been very different in different ages and countries, and there is little resemblance between the rude machines of the ancients and some of those which are now employed; but the harrow seems to have been nearly of the same form from the earliest times to which we are enabled to trace it on sculptures, medals, and other remains of antiquity.

It is a much more simple machine than the plough, and may even be held to be imperfect in any form in which it can be made; yet it is an instrument of great utility in tillage, and no other has yet been devised to supersede its use, or to equal it, for many of the purposes to which it is applicable. (Quart. Journ. of Agr. vol. i. p. 563.)

There were various stages in the gradual introduction of the modern harrow. The first implement used by men, for the purpose of covering seed, is generally the branch of a tree; to these soon succeeded more desirable substances, such as beams of wood; and then, again, two or more beams are fastened together: spikes, or teeth, are a much later improvement. Even now, in India (and there the natives but rarely alter their modes of culture or their implements), an instrument is used which is intended to produce the combined effects of the roller and the harrow. This, according to Mr. G. W. Johnson, “is nothing more in form than an English ladder made of bamboo, about 15 feet long, drawn by four bullocks and guided by two men, who, to increase its power, stand upon it, as they direct and urge on the cattle: again and again has it to pass over the same surface, and thus it causes a great waste of time and labour.”

Important as is the operation of harrowing, and second only to that of ploughing, it has often appeared to us that these implements have scarcely obtained the attention which is due to them, or that the improvements which have been carried into effect, than to the selection which appears generally to have been made. The operation is in many neighbourhoods so performed as to exhibit a prominent defect, either in the management of the farm, or in the construction of the implement: perhaps the blame may be fairly shared. It is admitted by all acquainted with the subject, that harrowing, especially on heavy soils, is the most laborious operation on the farm,—not so much, perhaps, on account of the quantity of power requisite for the draught (though this is sometimes considerable), as for the speed with which the operation is, or ought to be, accompanied; and yet it is frequently left to the charge of mere boys, and sometimes performed by the worst horses on the farm. If we examine a field, one-half of which has been harrowed by weak, inefficient horses, and whose pace was consequently sluggish, the other half by an adequate strength and swiftness of animal power, we shall find the furrows be much steeper; the latter comparatively firm and level, and completely in what would be called a husbandry-like manner. Scarcely any thing in farming is more unsightly than the wavy, serpentine traces of inefficient harrowing. The generality of harrows appear to us too heavy and clumsy to admit of that dispatch without which the work cannot be well done; and though it is evident that different soils demand different implements, of proportionate weight and power, yet, for the most part, harrows have been rather over than under-weighted, particularly when compared with a dray, or even the perjury of any kind. Harrowing has been so long regarded as an operation which must be attended with considerable horse-labour, that our attention has been turned to the inquiry, whether this labour might not be greatly reduced by lightening the harrows. Many, we think, would be surprised at the amount of reduction of which seed-harrows, at least, are capable, and where land is clear, to see how effective a gang of very light small-toothed harrows may be made. Having noticed the perfect manner in which seed-corn is covered by a common rake with wooden teeth, in some parts of Norfolk, a friend of ours constructed a gang of harrows on the following plan, and he states that they proved the most popular and useful implement of the kind on the farm. Pl. 15, fig. 1.

The frames are of ash, and as light as possible, the teeth (of iron) being but three inches long, exclusive of the part which enters the wood-work. They screw into the balks in the manner shown in Pl. 15, fig. 4.

It will be observed that the above four harrows are amply sufficient to cover a twelve-furrow stretch or ridge of 108 inches, but three will be wide enough for a three-furrow stretch of 90 inches, exclusive of a small portion of the furrows. If for some purposes the teeth be found too thick, every other tooth may be taken out; but for general purposes this will hardly be necessary. The two horses require, on this plan, to be kept quite level; for if one is suffered to go in advance of the other, a diagonal line is produced, by which the teeth will be made to cut much otherthan the furrows, and expose fresh ground. We are aware that, by the usual construction of harrows, a diagonal line of draught is required, in order to throw the teeth into a proper working position; but we are strongly inclined to the opinion, that the due execution of the implement ought to depend on its construction, and not on any particular mode of working it. Besides, the system of keeping one horse in advance of his partner is bad in principle; it is an unequal division of labour, the fore-horse being compelled to do more than his share of the work, which, under any circumstances, is always heavy enough.

We have stated that the above set of harrows are of wood. Their extraordinary lightness renders this necessary; but, for general purposes, we prefer those made of iron, the weight of which can be increased to any reasonable degree without adding much to their substance. This is important in working tenacious clays, which, by adhering to the clumsy wooden balks, considerably increase the labour, and at the same time impede the proper execution. In an experiment made between a pair of wooden harrows and a pair of iron ones, constructed on the same plan, having the same number, and precisely the same disposition of the teeth and balks, although the iron were
HARVESTING.

found to be 20 lbs. lighter than the wooden ones, yet they worked decidedly better and steadier than the latter; in fact they cut into the land, while the wooden ones rode, or rather danced, on the surface.

We now take up the consideration of the length and position of harrow-teeth. The common plan is to set them springing a little forward, and gradually increasing in length from the fore to the hind row. We think there is no advantage in this, but the contrary; for, if the action of harrows so constructed be carefully examined, it will be found the reverse of what it ought to be,—the hind part will be thrown up, and the fore-teeth, short as they are, will have to do all the work. In some experiments made with harrows, the fallacy of the idea, that an inequality in the length of the teeth was essential to the proper working of harrows, was made evident. For this purpose, a harrow was constructed on the old-fashioned plan of unequal and springing teeth in front; the whole of the teeth pointing backwards instead of forwards. Nothing could work better: there were no chucks and snatches, but all went on smoothly and steadily. We do not, from this circumstance, recommend harrows to be so constructed, but we have no doubt that each harrow should have all its teeth of equal length, and should stand perpendicularly from the balk.

Armstrong's Harrows.—These instruments differ from others in the form of their balks or framing, which are of iron, and of a zigzag shape, so arranged that the tooth or tine shall be fixed at each angle, in such manner that the lines formed by them shall be equidistant over the breadth of the land they are intended to cover. They can be adapted either for heavy or light work.

We now proceed to give a brief description of some other implements intended for the same operation, but of a more elaborate character.

Biddell's Extirpating Harrow.—This is a new implement, somewhat on the principle of Biddell's scarifier, and invented by Arthur Biddell of Playford. It is intended for breaking up land when it is too hard for the heaviest harrows, and for bringing winter fallows into a state of fine tillage. In working summer lands, by the shape of its teeth, it is calculated to bring to the surface all grass and rubbish; it will also be found generally useful for accomplishing fine tillage. The tines may be either used with points or with steel boats; and with the latter the skimming, or, as it is frequently called, the "broad-share" process, may be quickly accomplished. The weight is not found to be a disadvantage, but the contrary; and, being borne on high wheels, it does not require so much horse-labour as might be supposed. It is at present but in limited operation, though highly valued by those who have made use of it.

HARVESTING.

Fig. 2.

Each part consists of four bars of wood, technically termed bolts, and connected together by an equal number of cross bars of smaller dimensions mortised through them. The former of these bars may be 2½ inches in width by 3 inches in depth, and the latter 2 inches in width by 1 inch in depth. The longer bars are inclined at a certain angle to the smaller, so as to form the figure of a rhomboid, and they have inserted into them the teeth at equal distances from each other. This inclination of the longer bars is made to be such, that perpendiculars from each of the teeth, falling upon a line drawn at right angles to the line of the harrow's motion, shall divide the space between each bar into equal parts; so that the various teeth, when the instrument is moved forward, shall equally indent the surface of the ground over which they pass. (Quart. Journ. Agr.)

HARVEST (Germ. herbst.) In agriculture, the period at which any crop is reaped. The term is more commonly applied to the crops of corn or hay.

HARVEST FLYES, Cicadians. See Locusts.

HARVEST-HOME. A sort of feast given by the farmer, after harvest, to the labourers and others that have assisted in cutting and securing the crops. The term is sometimes also applied to the song made use of on the occasion.

HARVESTING. The operation of pulling, cutting, rooting up, or gathering field crops, and drying or otherwise preparing them for being stored up for winter use. The first harvest which occurs in Britain and similar climates is that of the forage grasses, or other plants made into hay; the next is the harvest of cereal grasses, or of corn crops; and the third, the potato harvest, or harvest of root crops, such as potatoes, carrots, turnips, mangel-wurzel, &c.

There is also the harvest of occasional crops, such as that of rape-seed, turnip-seed, dyer's-woad, hemp, flax, and various other articles. The commencement of harvest is necessarily regulated by the state of the weather, and varies in different seasons, even when the weather is favourable, from the middle of July to the end of August; while, in some years, and in exposed situations, it is still later. It is, therefore, an object of importance to the farmer to ascertain the exact time when it may be begun, for he must employ extra hands to perform the work; and as it only lasts during a comparatively short period, they receive high wages, and are maintained at a heavy cost. It is also attended with the most anxious solicitude, for it is a business which cannot be for a moment neglected; and the man who wishes to get it rightly managed, must superintend it, without intermission, from the dawn of the day until its final close. He should previously get rid of all other work, and make every preparation for the due performance of this; the barns should be thoroughly swept out, both roof, walls, and floors; the stack-frames repaired, and every tool should be in complete condition. The straw-bands should be in readiness for tying the sheaves, as well as the ropes for securing the stacks; and arrangements should
be made in the house for the regular supply of whatever is to be furnished to the labourers, so that every unnecessary delay may be avoided. The strictest order should also be maintained; but the work will never be well performed unless it be conducted with perfect good temper. Fortunately, the crops do not usually ripen at the same precise period; that of rye being the earliest, and wheat about a fortnight later; some of the early species of oats and barley come in between the rye and wheat; but barley more generally comes afterwards, followed by some of the later kinds of oats. Grain, if not reaped until the straw is wholly yellow, will be more than ripe, as the ear generally, except in late seasons, ripens before the entire of the straw: and it is observable that the first reaped usually affords the heaviest and fairest sample.

The indications of ripeness in wheat are few and simple. When the straw exhibits a bright golden colour from the bottom of the stem nearly to the ear, or when the ear begins to bend gently, the grain may be cut. But—as the whole crop will not be equally ripe at the same time—if, on walking through the field and collecting the greenest heads, the kernels can be separated from the chaff when rubbed through the hands, it is a sure sign that the grain is then out of its milky state, and may be reaped with safety; for although the straw may be green to some distance downwards from the ear, yet if it be quite yellow from the bottom upwards, the grain then wants no further nourishment from the earth, and, if properly harvested, it will not shrink. These tokens will be found to sufficiently indicate the ripeness of wheat, barley, and oats; but that of rye arises from the straw losing some of its golden hue, and becoming paler.

The usual practice in England is to cut down all grain before it is quite ripe, and to leave it in shocks, or, in the ease of barley, on the ledge, until the grain is perfectly matured and hastened; and the same practice prevails in Scotland. Experience, however, has occasioned a remarkable distinction in the mode of harvesting barley in the two portions of Great Britain just mentioned. In England, barley is usually cut with the scythe, treated like hay in the saving, and put loose into the rick or mow. In Scotland, it is cut, as in Ireland, generally with the reap-hook, and, when sufficiently dry, bound up and stacked. The cause of this different treatment is the difference of climate. See Barley, Reaping, Winnowing.

HARVEST-MOON. That lunation about harvest-time when the moon at full rises nearly at the same hour for several nights. HASEL, HAZEL, or STOCK NUT (Corylus avellana). This small, bushy tree is common everywhere in our hedges and copses, and also grows wild in most parts of Europe. The leaves are two inches wide, doubly serrated, light green, downy, especially beneath. The catkins are barren, clustered, or panicled, grayish, long, and pendulous, opening in the early spring before the leaves appear, and, indeed, formed during the preceding autumn. The ovate scaly buds, containing the fertile flowers, become conspicuous at the same time by their tufts of crimson stigmas. The nuts, two or three from each bud, are sessile, roundish-ovate, half covered by the jagged outer calyx of their respective flowers, greatly enlarged, and permanent. The wood of the hazel-tree is used in England for making hoops for casks, hurdles, crates, springles to fasten down thatch, fishing-rods, &c. It is also reported to make excellent charcoal for drawing, of the preparation of which, and of the whole history of this plant, Dr. Hooker gives a full account, annexed to an admirable figure. It was formerly much used for making gunpowder. (Eng. Flor. vol. iv. p. 157.) See FILBERT.

In the country where yeast is scarce, they twist the slender branches of hazel together, and steep them in ale yeast during its fermentation; they are then hung up to dry, and at the next brewing are put into the wort instead of yeast. The chips of this wood are used to fine wines. (Phillips's Fruits.)

HATCHING. See Incubation.

HAULM. A name given to the stalks of beans and pea. When well harvested, these form a very hearty species of fodder. The stalk of the beans is indeed tough and somewhat woody, and is therefore commonly thrown out as farm-yard litter; but the coving chaff is very good manger-meat; and even the stalk, if bruised and cut, and then steamed, would be found useful in a farm-stable.

Pea haulm is very generally given as rack-meat to cart-horses instead of hay, for which purpose it is well adapted, being succulent and nutritious, and nearly as much relished as hay; although it may not go quite so far, yet there is great saving in its use. But both these and all other kinds of straw haulm should be given as fresh as possible from the field, for they grow brittle, and lose a portion of whatever sap they possess, by exposure to the air; if long kept they grow musty, and in that state neither are wholesome nor will be eaten by farm-horses. Pea haulm should be given cautiously, as it is flatulent, and apt to occasion colic; it is also said to be productive of bots; but that, if true, is not so peculiar a property as to prevent its use. Sheep are extremely fond of haulm; much so, indeed, that it is by no means uncommon for farmers who keep large flocks to grow pease chiefly with a view to it as winter food in pinching seasons; the seed being in that case generally sown broadcast, both to preserve the succulence of the haulm, and to save the trouble of the drill culture. (Curt. Husb. vol. i. p. 133; vol. ii. pp. 219, 463.) See Pea, and Beans.

HAVER. A name given to oats (particularly to wild oats) in some parts of Britain; hence haver meal is meal made from oats by grinding and siftling through a proper sieve for the purpose. In some parts of Scotland a thick oat cake is used, and called a haver meal bannock.

HAWKBIT.
HAWKWEED. 

HAY.

cious plants of easy culture. The indigenous species found in Britain are four.

The autumnal hawkbit (A. autumnalis) is a very common and troublesome weed in all meadows and pastures. It varies very much in luxuriance, and is often found thriving in exceedingly poor land newly turned up. The root is abrupt, with very long, simple, lateral fibres. Leaves several, almost entirely radical, lanceolate, deeply and unequally toothed or pinnatifid. The stalks are several, ascending or spreading, branched, from 6 to 18 inches high. Each stalk is hollow internally, containing a loose, white, cottony tuft. The flowers are bright yellow, not large, often reddish underneath. As these are all perennial weeds and encumber the ground, they should be rooted up in spring. (Eng. Flor. vol. iii. p. 350.)

HAWKWEED (Hieracium, from hierax, a hawk, being supposed to sharpen the sight of birds of prey). A very numerous perennial genus, generally inhabiting mountainous or woody situations. They are, for the most part, pretty flowering plants, with yellow blossoms, but a great number are mere weeds. The herbage, in general, is milky, and more or less bitter; but these qualities are, in some instances, hardly perceptible. The dwarf herbageous kinds are remarkably adapted for rock work, or the front of flower borders, the taller kinds at the back; they may be increased by seeds, or divisions. The annual species need only be sown in the open border.

Sir J. E. Smith describes no less than eighteen distinct indigenous species, which it would carry me too far into detail to particularize.

Ten or twelve species of hieracium have been found by botanists in the United States, and 14 in the British provinces. One called the veined hieracium, or hawkweed (H. venosum), is a frequent plant in clearings and woodlands in New Jersey, Pennsylvania, and other Middle States, where it flowers in May and June. It has a perennial root, and stem 1 to 2 feet high. A few years since, this plant was announced as a certain antidote against the poison of the rattlesnake. But its specific virtues need to be further tested before they can be regarded as fully proven. A great many specifics and antidotes are vaunted by credulous, or designing persons, for the poison of reptiles as well as the bite of a mad dog, and persons who have taken them and escaped any serious mischief, have led others to believe in the virtues of the remedies when the patients would have recovered without. In this way the most inert and inefficient prescriptions often get the credit of what properly belongs to the agency of common homely appliances, or the wonderful restorative powers with which a kind Providence has endowed both man and beast.

HAWTHORN, WHITETHORN, or MAY (Crataegus oxyacantha). A common small tree or shrub, but beautiful in its appearance, and fragrant in odour. The hawthorn grows almost everywhere in thickets, copses, hedges, and high open fields. The wood is very hard, with a smooth, blackish bark, and, like the whitebeam hawthorn (Prumis aria), is converted into axle trees and handles of tools. The branches have lateral, sharp, awl-shaped thorns. The leaves are alternate, deciduous, on longish, slender stalks; smooth, deep-green, veiny, an inch or two long, tapering at the base, or wedge-shaped, and more or less deeply three-lobed, with crescent-shaped stipules. The flowers are white, terminal, white, occasionally pink or almost scarlet. The fruit (called haws) is mealy, insipid, dark red, occasionally yellow, furrowed externally, and very hard. Birds are fed with the fruit all the winter long; but the haws may be more usefully employed in fattening hogs. In Kamschatka they are eaten by the peasants, and fermented into wine. The common hawthorn blows in May, and can be propagated from seed, which must be kept in sand through the winter, and sown in spring. The young plants will be fit to place out in two years. There are several varieties of this species, among others the celebrated Glastonbury thorn, which blossoms sometimes as early as Christmas. The double bloomed hawthorn is one of the greatest ornaments of our pleasure-grounds, whether it be kept as a shrub, or trained as a tree.

The yellow-berried hawthorn, which was originally brought from Virginia, has a double recommendation to the shrubbery, for its buds are of a fine yellow in the spring, and its fruit, which is of the colour of pure gold, hang on the branches nearly the whole of the winter, giving great variety to the plantation. Evergreens should never be planted without a few of these shrubs being intermixed to enliven them in the winter months. The hawthorn is peculiarly adapted for small lawns or paddocks, where larger trees cannot be admitted. When standing singly, the hawthorn often reaches to the height of 25 or 30 feet, with a trunk from 4 to 8 feet in circumference.

In hushandary, these shrubs are called quicksets; and when kept well cut, they form hedges, scarcely less impregnable than those composed of holly. The clipping of hedges and trimming of trees is certainly advantageous to the farmer, although it adds nothing to the beauty of rural scenery. Hawthorn hedges appear to have come into use, in England, about the time of Charles II.; as Evelyn observes in his Sylva, "I have been told of a gentleman who has considerably improved his revenue, by sowing haws only and raising nurseries of quicksets, which he sells by the hundred, far and near. This is a commendable industry, and any neglected corner of ground will fit this plantation."

See Thorns.

HAY (Germ. heu, Du. hooi). Any kind of grass cut and dried as fodder for cattle. Hay constitutes the chief dependence of the farmer and others as winter food for their horses and cattle. The sale of hay within the bills of mortality, and 30 miles round the cities of London and Westminster, is regulated by the act 36 Geo. 3, c. 38. It enacts, that all hay shall be sold by the load of 36 trusses, each truss weighing 50 lbs., except new hay, which is to weigh 60 lbs. till the 4th of September, and afterwards 56 lbs. only; so that till the 4th of September, a load of hay weighs exactly a ton, but thereafter only 18 cwt. There are three public markets in the metropolis for the
HAY.

HAYMAKING.

sale of hay and straw, Whitechapel, Smithfield, and the Haymarket.

When horses are fed on hay, it is a matter of dispute whether the light and apparently acrid grass of uplands, or that of more fertile natural meadow ground, or the rich produce of the artificial grasses, is to be preferred. This must, however, depend on the quantity of corn with which they are supplied. When that is abundantly furnished, there can be no doubt that the former will be found better for their general health, and especially for their wind; but as farm-horses are usually limited in their consumption of grain, and the slowness of their movements renders the clearness of their wind a matter of comparatively little moment, the other kinds will be found the best adapted to support their strength. In gentlemen's stables no other than meadow hay is generally admitted; and it is in all respects the best. But farmers find more profitable uses for it in the feeding of fattening-stock and cows; and clover, either alone or with rye-grass, sainfoin, or tare hay, though coarser, answers every necessary purpose for farm-horses, more especially when cut into chaff, and used along with straw. Sainfoin is commonly esteemed the first, and clover the next, in quality; but taro, if it be cured, is very hearty food. Old hay, as having longer undergone that slow process of fermentation by which the sugar that it contains is developed, is far more nutritive and wholesome than new hay. Mow burnt hay is more injurious to horses than to any other of the domestic animals, and is a fruitful source of disease.

It is an excellent plan, especially when hay has been exposed to continued wet weather, to add to it a portion of common salt. It not only induces live-stock to consume it with avidity, but it prevents mouldiness or mow-burning; it is usual to put about half a bushel of salt to every load of hay: it may be spread by hand, or through a sieve. Mr. Woods, of Ingatestone, in Essex, has employed it for thirty years; his plain, unvarnished statement need not be supported by any other. He says, "I use about a quarter of a peck at each haying, thinly spread, which I find is about four bushels to a stack of twenty loads. I am fully satisfied that double the quantity would be much better. In a particularly wet season, a few years since, I used twelve bushels to a stack of forty loads, the whole of which was consumed by my own horses, and I never had them in better condition. I am so fully convinced of the benefit of salt to hay, that while it is allowed duty free, I shall use it in all seasons." (Johnson on Salt, p. 100.) The avidity with which animals consume salted hay is not so generally known as it ought to be; I will give, therefore, a fact related to me a short time since by Mr. Law, of Reading, in Berkshire, had, in the season of 1824, a parcel of sourr'shy hay from a meadow on the banks of the Thames, which both he and his men despised of rendering the least value; it was, therefore, stacked by itself, and well salted; the quantity supplied was large, but Mr. Law did not know the exact proportion. When the period arrived that his sheep wanted a supply of hay, Mr. Green directed his shepherd to use the salted inferior hay first; and, to his surprise, the sheep consumed it with the greatest avidity. The stack being finished, the shepherd was directed to supply them now with the best hay he could find of other stacks of fine meadow hay. He came, however, the next morning to his master, and made the following remark: "We, sir, must have made a great mistake, and forgotten which stack we salted, for our sheep will not eat the hay which we think the best."

As the hay grasses do not thrive in the Southern United States, the principal supply of this provender is sent pressed in bales or packages from the Western, Middle, and Southern States. In those states where hay constitutes a principal product of the farms, New York stands first and Pennsylvania second. In his observations, relative to the hay crop of 1842, Mr. Ellsworth observes, "Ohio, Indiana, Illinois, Michigan, and Missouri, though devoting comparatively little attention to its production, yet seem to be making some advance in the same; and accordingly there has been some increase the past year, though doubtless not a very material one. Some damage was experienced from the invasion of the army worm, but not enough to lessen the crop to any great amount. Though reliance is still placed on the prairie hay, yet there is a gradual improvement with respect to the introduction and cultivation of the tame grasses. The low price of grain in New Orleans will no doubt lessen the demand for pressed hay, which has heretofore been a considerable article of export from the states bordering on the Ohio river and its branches. The whole number of tons of hay raised in the United States in 1842, is estimated to have been 14,053,555."

HAYMAKING. The operation of cutting down, drying, and preparing grasses and other forage plants for being stacked for winter use. The plants are mown down at the time when they are supposed to contain, diffused throughout the whole plant, a maximum of nutritious juices; viz., when they are in full flower. Too often this period is exceeded, and the nutritive property of the plant suffers; for it is a well-known fact that the saccharine juices of a plant disappear in the progress of the ripening of the seed. Dry weather, and, if possible, that in which sunshine prevails, is chosen for this operation; and the mown material is spread out, and turned over two or three times in the course of the same day in which it is cut. In the evening it is put into small heaps. In the morning of the second day these heaps are spread out, and turned over two or three times; and in the evening they are formed into heaps, somewhat larger than they were the day before. If the weather has been remarkably warm and dry, these heaps, in the course of the third day, are carted away and made into a stack; but if the weather has been indifferent, the process of opening out the heaps and exposing them to the sun is repeated on the third day, and stack-making is not commenced till the fourth. The grand object in making hay is to preserve the colour and natural juices of the herbage, which is best done by continually turning it,
so as never to expose the same surface for any
depth of time to the direct influence of the sun.
In stacking hay, the object is to preserve the
green colour, and at the same time induce a
slight degree of fermentation, which has the
effect of rendering the fibres of the plants,
which compose the hay, more tender, and
changing a part of the parenchymous matter
into sugar, on the same principle as is effected
by malting barley. This sweet taste renders
the hay more palatable to horses. The best
general directions for haymaking will be found
in the following-extract from the "Agricultural
Survey of Middlesex", although the various
kinds of hay, and different soils and situations
with which the farmer is connected, are so
ever numerous, that such directions can, of
necessity, have only a very general applica-

Mr. Middleton observes, when speaking, be
it remembered, of haymaking in Middlesex,
"In order that the subject may be more clearly
understood, I shall relate the particular opera-
tions of each day, dividing the work into
particular parts as they are performed,
from the moment in which the mower first
applies his scythe, to that in which the hay is
secured, either in the barn or in the stack.

"First Day.—All the grass mown before nine
o'clock in the morning is tedded (or spread),
and great care taken to shake and strew it
evenly over all the ground. Soon afterwards
it is turned, with the same degree of care and
attention; and if, from the number of hands,
they are able to turn the whole again, they do
so, or at least as much of it as they can, till
twelve or one o'clock, at which time they dine.
The first thing to be done after dinner is, to
rack it into what are called single windrows;
that is, they all rake in such a manner, as that
each person makes a row, which rows are
three or four feet apart; and the last operation
of this day is to put it into grass-cocks.

"Second Day.—The business of this day com-
ences with tedding all the grass that was
mown the first day after nine o'clock, and all
that was mown this day before nine o'clock.
Next, the grass-cocks are to be well shaken
out into staddles (or separate plats) of five or
six yards diameter. If the crop should be so
thin and light as to leave the spaces between
these staddles rather large, such spaces must
be immediately raked clean, and the rakings
mixed with the other hay, in order to its all
drying of a uniform colour. The next business
is to turn the staddles, and, after that, to turn
the grass that was tedded in the first part of
the morning, once or twice, in the manner de-
scribed for the first day. This should all be
done before twelve or one o'clock, so that the
whole may lie to dry while the workpeople are
at dinner. After dinner, the first thing to be
done is, to rake the staddles into double wind-
rows; in doing which, every two persons rake
the hay in opposite directions, or towards each
other, and by that means form a row between
them of double the size of a single windrow.
Each of these double windrows are about six
or eight feet distant from each other. Next, to
rake the grass into single windrows; then the
double windrows are put into bastard-cocks;
and, lastly, the single windrows are put into

grass-cocks. This completes the work of the
second day.

"Third Day.—The grass mown and not spread
on the second day, and also that mown in the
early part of this day, is first to be tedded in
the morning; and then the grass-cocks are to
be spread into staddles, as before, and the bas-
tard-cocks into staddles of less extent. These
lesser staddles, though last spread, are first
turned, then those which were in grass-cocks;
and, next, the grass is turned once or twice
before twelve or one o'clock, when the people
go to dinner usual; when the weather has
proved sunny and fine, the hay which was last
night in bastard-cocks will this afternoon be
in proper state to be carried. It seldom hap-
pens, in dry weather, but that it may be carried
on the third day. But if the weather should,
on the contrary, have been cool and cloudy, no
part of it, probably, will be fit to carry. In that
case, the first thing set about after dinner is, to
rake that which was in grass-cocks last night
into double windrows; then the grass which
was this afternoon raked is to be well shaken
into single windrows. After this, the hay which
was last night in bastard-cocks is made up into
full-sized cocks, and care taken to rake the hay
up clean, and also to put the rakings upon the
top of each cock. Next, the double windrows
are put into bastard-cocks, and the single
windrows into grass-cocks, as on the preceding
days.

"Fourth Day.—On this day the great cocks,
just mentioned, are usually carried before din-
ner. The other operations of the day are such,
and in the same order, as before described, and
are continued daily until the hay-harvest is
completed.

"In the course of hay-making, the grass
should, as much as possible, be protected, both
evening and day, against rain and dew, by cock-
ing. Care should also be taken to proportion
the number of hay-makers to that of the mowers, so that there may not be more grass
in hand, at one time, than can be managed ac-
cording to the foregoing process. This propor-
tion is about 20 hay-makers (of which number
12 may be women) to four mowers: the latter
are sometimes taken half a day, to assist the
former. But in hot, windy, or very dry weath-
er, a greater proportion of hay-makers will
be required than when the weather is cloudy
and cool.

"It is particularly necessary to guard against
spreading more hay than the number of hands
can get into cock the same day, or before rain.
In showery and uncertain weather, the grass
may sometimes be suffered to lie three, four, or
even five days in swath. But, before it has
lain long enough to become yellow (which, if
suffered to lie long, would be the case), par-
ticular care should be taken to turn the swaths
with the heads of the rakes. In this state it
will cure so much in about two days, as only
to require being tedded a few hours, when the
weather is fine, previous to its being put to-
gether and carried. In this manner, hay may
be made and stacked at a small expense, and
of a good colour; but the tops and bottoms of
the grass are insufficiently separated by it."

HAY-RAKE, or HAY-SWEEP. An imple-
ment contrived for the purpose of collecting
HAY-KNIFE.

and conveying hay to the stack in an easy and expeditious manner after it has been put into rows. See Rakes.

HAY-RICK. A sharp instrument employed for cutting hay out of the stack.

HAY-RICK. (Com. to Board of Agr. vol. vii. p. 374) describes an improved hay-rick which admits very freely the cool air to check the fermentation. A channel or gutter, a foot wide and deep, is cut through ground marked out for the rick, and two across, which is 13 yards by 9. Two chimneys are introduced, like the common hay tunnels, only these go full home to the earth, which being drawn up as the rick is forming, and the channels previously covered with fagots, except where the chimneys are placed, leave them open at all points; and let the wind blow from what quarter it may, the current is uninterrupted.

HAZEL. See Hazel.

HEAD-LAND. A term applied to the lands or ridges in fields, on which the plough turns in cultivating them. As much soil is continually accumulating on them, by means of the frequent ploughing of the field, it is a common plan to form them into composts with lime or other manures.

HEAT. In horsemanship, a term used on the turf, to denote a certain distance which a horse runs on the course. A race may consist of one or more heats, and “the best of three heats” are common at most races; but there is never more than one heat for a race at Newmarket. See Temperature.

HEALTH. In a general sense the term health is applied to waste land in which the prevailing plants consist of one or more of the common species of heath.

HEALTH, HEATHER, or LING (Calluna and Erica). A very large and varied genus of plants, of which the following species are indigenous to Great Britain:

1. Common heath (Calluna vulgaris, Sal. The Erica communis of Linnaeus). This plant covers many hundreds of acres in the Highlands of Scotland, in Ireland, and in similar climates on the continent. It attains in many places the height of three or four feet; and is much used for thatching houses, making besoms, and for a variety of other purposes. The tender tops form a substitute for marrasses in Highland cottages; and they are also eaten green and in a dried state by horses, cattle, and sheep, in countries where the grasses and clover do not begin to grow till late in the spring. The tender tops also furnish food for grouse.

2. Cross-leaved heath (Erica tetralix). In this shrub the roots are creeping, stems erect, from four to six or eight inches high. Leaves crowded, spreading four in a whorl, revolute, downy, glaucous beneath. Flowers remarkable for their delicate wax-like hue of every shade of rose-colour, sometimes snow-white, on hairy cottony stalks collected into a dense, round, terminal cluster, all elegantly pendulous to one side. It is wonderful that this most elegant and not uncommon plant is scarcely delineated at all by the old authors, nor by any of them correctly.

3. Fine-leaved heath (E. cinerea), found plentifully on dry turfy heaths everywhere. It grows on a stem a foot high, or more, with numerous upright, round, hoary, flowery, and leafy branches. The flowers are crimson, everlasting, with a tinge of blue or gray, occasionally pure white.

4. Cornish heath (E. vagans), growing abundantly in Cornwall: stem woody, two feet high, copiously and determinately branched, with a smooth, pale, deciduous bark; leaves evergreen, smooth.

Mr. J. Hall (Com. to Board of Agr. vol. vi. p. 381) speaks favourably of the advantages to be derived from heath in the feeding of stock, and also asserts that an infusion of the finer parts of heath, when cut young and in bloom, is preferable to tea.

HEATH GRASS (Triodia decumbens). The genus to which this species belongs consists of hard, rigid, perennial grasses, with leafy stems. Inflorescence variously panicked. The decumbent heath grass grows frequent in spongy bogs, and on barren, sandy, mountainous ground. The root is very slightly creeping, with strong fibres. The whole plant is harsh and rigid, lying close to the ground, except when in flower. The stem is from 4 to 12 inches long, jointed, bent, leafy, and very smooth. The leaves are linear, striated, rather glaucous, smooth, except towards the points, where the rib and edges are very rough. (Smith's Eng. Flor. vol. i. p. 131.)

HEATH, SEA (Frankenia). Of this maritime decumbent genus of plants there are two species, natives of these islands.

1. The smooth sea-heath (F. levis) is a perennial, flowering in July, found common on muddy salt-marshes, chiefly on the eastern shores of England. It has a woody root; the stems are quite prostrate, forked, slightly downy, with leafy, partly ascending branches. The leaves are somewhat glaucous, about a quarter of an inch long, revolute, fringed at the base, convex, and smooth above. The flowers spring from the forks of the stem, partly terminal, sessile, solitary, and flesh-coloured.

2. Powdery sea-heath (F. pulverulenta). This is a very rare species, much resembling the last, but annual, and flowers in July. The root and stems the same as the former: the leaves, which are smooth and green above, are hoary, as if powdery, beneath; opposite or four together, single ribbed, and revolute. The flowers are pale red. (Smith's Eng. Flor. vol. ii. p. 186.)

HEATHY LAND. Ground which is covered with heath. In many districts of the kingdom of Great Britain, there are immense tracts of this kind of land, that, in their present state, are of little value, except for the support of a few sheep; but which, by proper cultivation, might afford useful crops. They, however, differ much in the nature of the soil. The best mode of reclaiming these lands is by draining, deep trenching, or ploughing, and spreading upon them any calcareous matter, such as lime, chalk, or marl. And it is very desirable, in many instances, to provide them shelter by plantations of timber trees. See Plantations.

HEDGE. A living wall formed of woody
plants, sown or planted in a line, and cut or clipped in such a manner as to form a compact mass of any degree of width or height that may be required, either for the purpose of shelter, separation, or defence. The fences most generally used in agriculture are made of the whitethorn, because it has spiny branches, and forms a strong defence against cattle. Fences for the purposes of shelter and separation are chiefly used in gardening, and for the most part are formed of evergreen shrubs, such as the holly, yew, box, &c.; or sub-evergreens, such as the privet; of flowering shrubs, such as the Cytisus japonicus; or of deciduous shrubs or trees, with persistent leaves, such as the hornbeam and beech.

In the management of hedges of every description, an important point is to keep them thick, and impervious to wind or animals, near the ground; for which purpose the section of the hedge requires to be made broader at the base than at the top, in order that the exterior leaves in every part of the hedge may enjoy in an equal degree the influence of light, air, and perpendicular rains. Mr. Stephens (Quart. Journ. of Agr. vol. iv. p. 535, to 378, by Messrs. Montgomery, Grigor, and Manson. In the same volume, p. 336; there is an essay on the cultivation of the common elder (Sambucus nigra) for hedges. Sir John Sinclair also recommends the tala plant as a substitute for thorn in hedges. (Quart. Journ. of Agr. vol. ii. p. 408.) It is a small prickly shrub, growing wild in various parts of South America, and which has been extensively used for fences by the Scotch farmers who have settled near Buenos Ayres. An "Old Hedger," in the Quart. Journ. of Agr. vol. v. p. 505, also gives the result of his experience and practice in hedge-making. The late Francis Blakie of Holkham saw the importance of paying more attention than is customary with him to the plantation of fences, and the management of hedgerow timber; and in his excellent little work on this subject, he told him (and his experience was of perhaps the most difficult of all soils upon which to rear good hedgerows), "There may be some difference in opinion as to the best method of planting and rearing quickset (whitethorn) hedges, but I think there can be none in respect to the propriety of thoroughly cleaning and preparing the ground in the first instance; and all experienced men will agree, that it is not advisable to plant a new hedge upon the same spot where an old one had been recently grubbed up, unless under unavoidable circumstances, such as boundary fences, &c.; in that case the ground should be well loosened, allowed for a year or two, and have fresh earth or compost added. The better the ground is prepared, the sooner will the hedge arrive at maturity, and the longer will be its duration.

The practice in this country (Norfolk), even on our lightest soils, is to put the quicksets (here called layers) horizontally into the side of the bank, raised from the ground five feet wide, and ditto, of a proportionate depth; and I have never seen whitethorn hedges raised quicker or better than in this country, and all upon that principle. I must, however, acknowledge, that although the Norfolk farmers very generally excel in raising hedges, they but too frequently err in the future management of them; youth is succeeded by infirmities; there is no prime of life.

There is another error which frequently occurs where quicksets are planted on the sides of banks; that is, in not varying the height of the line of quick in the bank according to the nature of the sides. On the management of hedgerow timber, the directions of Blakie are equally excellent. He says, "It is not necessary for me to particularize all the varieties of forest trees usually planted in hedgerows. It is sufficient, in exemplification, to say, beech, ash, and firs are not only ruinous to fences, but are also otherwise injurious to farmers; while oaks, narrow-leaved elm, and ditto, Italian poplars do comparatively little injury; and as to the age of plants, it surely must be obvious that a thrifty transplanted nursery tree of three years' growth is more likely to succeed, when properly planted in a hedgerow, than a puny yearling drawn out of a seed-bed, with its root like a piece of whipcord; or a tender sapling, of six or seven years' growth, drawn out of a thick wood, whence it had not been previously transplanted.

In planting, the usual practice is to lay the roots of the forest-tree plants horizontally into the bank along with the whitethorns, and to cut their heads or tops off close to the ground, in the same manner as the thorns; a moment's reflection will show the absurdity of this practice. A surface-rooted plant, like the whitethorn, will thrive if laid into the bank horizontally, or nearly so; but a deep-rooted plant, such as the oak, is not likely to thrive if treated in that manner. The roots of oaks strike deep into the ground; consequently, the plants should be set perpendicularly, and their heads or tops should be cut off at the time of planting. But suppose that an oak plant, when laid into the bank horizontally along with the quicksets, does grow, and even prospers for a time, which it may do when the extremities of the roots are bent downwards by the pressure of the earth in the bank above, and the plant in consequence finds nourishment and support from the earth below; the top of the plant will then grow up among the row of thorns, and be protected by them until the hedge is cut (which, in process of time, it must be): the oak plant will then be left exposed, and as the stem will have bent upwards, at a sharp angle from the face of the bank, the top of the tree (when agitated by the wind) will act as a powerful leverage, and have the effect of twisting and breaking the crooked roots of the plant in the bank.

"These remarks are, in some degree, applicable to all forest trees planted in hedgerows, but more particularly to deep-rooted ones.
The method which I recommend for planting forest trees generally in hedgerow, but more particularly oaks, is as follows: Let the quicksets be laid in, and the bank finished in the usual way; then select transplanted trees of 2 or 3 years' growth, fresh drawn from the nursery. The broken roots and tips of the long fibres may be cut off; then push the spade down perpendicularly into the bank between the roots of the quicksets; press the spade from side to side, as to make a cleft opening, into which put the root of the plant as deep as it had before stood in the nursery; tread the earth firm to the root, and face the bank up, as before: leave the tops of forest-tree plants uncut at the time of planting, unless when they are bushy-headed, and without leaders or top-shoots; in that case a few of the larger side shoots may be cut in, that is, the extremities of the branches shortened. It is a most pernicious practice to cut the tops of young forest trees at the time of planting, and should only be adopted in particular cases.

"The time most proper for planting hedgerow trees and quicksets is autumn, or early in spring; and the work should never be delayed till late in spring, if it can be avoided. But when it is expected that the bark and the timber will heal over the wound and become united. If this operation is completed when the branches are young, or mere saplings, the tree in a vigorous growing state, and a few only of the branches cut off in one season, the object will be obtained, without injuring the growth of the tree. But the system, from having been misunderstood, has been misapplied, and carried to an alarming extent, doing incalculable injury, not only to individuals, but to the country at large. Immense numbers of large boughs have been amputated from the trunks of trees, in the vain hope of the timber growing over the wounds, and uniting with the stumps of the boughs left in the body of the tree; the bark and sap-wood does indeed sometimes grow over such wounds, but the stumps of the branches enclosed go to decay, become a canker in the bole of the tree, and the result is calamitous. It is the ready extension of the bark over the wounds in trees which has been the means of misleading so many people; because, as they see that the bark unites, they take it for granted that the woody fibres do so also; and so, in fact, the growing part of the tree will do, but the stump of the amputated arm becomes a dead substance, and cannot unite with a living one. On the whole, it is a dangerous practice to cut large boughs close to the stems of trees, particularly old and unthrifty trees. Young thriving trees will succeed, if close pruned, to a certain extent; but old, stunted, or full-grown trees, necer.

"Snag pruning is a very pernicious practice; it is performed by cutting the boughs off several inches from the bole or stem of the tree. In old trees, those stumps act as conductors for wet into the body of the tree; in young trees the bark of the stumps throw out young shoots, which flourish for a time, but the heart-wood of those stumps decays, and has a similar effect to the stumps of boughs in old trees, which do not throw out young shoots."
HELIOTROPE.

Foreshortening, or cutting in, is an approved method of pruning, and is admirably adapted to training hedgerow trees, to benefit the landlord without doing much injury to the tenant. This operation is performed by shortening the over-luxuriant side branches, but not to cut them to a stump, as in snag pruning; on the contrary, the top only of the branch should be cut off, and the amputation effected immediately above where an axillary (side shoot) springs from the branch on which the operation is to be performed: this may be at the distance of two, four, or any other number of feet from the stem of the tree; and suppose the axillary branch which is left (when the top of the branch is cut off) is also over-luxuriant, or looks unsightly, it should also be shorted at its sub-axillary branch, in the same manner as before described.

The branches of trees pruned in this manner are always kept within due bounds; they do not extend over the adjoining land to the injury of the occupier, at least not until the stem of the tree rises to a height (out of the reach of pruning) when the top branches can do comparatively little injury to the land. By adopting this system of pruning, the bad effects of close and snug pruning will be avoided, the country will be ornamented, and the community at large, as well as individuals, benefited."

(Blake, On Hedges and Hedgerow Timber.) See Fences and Hawthorn.

A great deal of valuable information upon the subject of hedges in the United States will be found in almost every agricultural periodical, in many of which the merits of the Virginia thorn, Newcastle-cockspur, English black-thorn, Buck-thorn, Osage orange, &c. &c. and their adaptations to particular parts of the country, are discussed. See particularly the Essays of Caleb Kirk, of Newcastle county, Delaware, in the first volume of the American Farmer, and the further communications on the same subject in other parts of the same valuable work.

HEDGE-BIRDS. Various kinds of birds seek for shelter or food in hedges. Some of these are more or less destructive of grain and fruits, as but few live exclusively on insects. It cannot, however, be doubted that the advantages derived from birds in the destruction of caterpillars, and various kinds of worms and insects which destroy the crops, more than compensate for the small tithe of seeds, grain, or small fruit they are able to exact during the short period of harvest.

HEDGE MUSTARD (Sisymbrium). A genus composed for the most part of worthless annual and biennial plants, flourishing in the open ground in any soil. The indigenous species are three, all annuals.

1. The common hedge mustard (S. officinale), growing in waste ground, by road-sides, and on banks; very common in England; flowering in June and July. According to Haller, hedge mustard springs up wherever houses have been burnt. The herb is of a dull green, minutely hairy or downy; the stem solitary, two feet high, erect, with numerous horizontal branches, leafy, round, clothed with fine deflexed bristles. Leaves hyrate, their lobes runcinate, unequally toothed; the upper ones narrowest. The flowers are pale yellow, small, in little corymbose heads, soon becoming very long, straight, close clusters of erect, tapering pods, finely downy, rather more than half an inch long, on very short stalks. Seeds not numerous, about six in each cell. This species was once used as a stimulating expectorant, but it is now deserted out of favour.

2. The broad hedge mustard, or London rocket (S. irio), grows chiefly about London, and in habit is somewhat like the preceding species; but the herbage is of a lighter green and entirely smooth. The leaves are pinnatifid, runcinate, acute, the upper lanceolate, with hastate base; the seed-pod is two inches long, rough when ripe; the seeds are very abundant. It is sometimes used as a heating pot- herb.

3. Fine-leaved hedge mustard or fixweed (S. sophia). In this species the root is small and tapering, and the whole plant of a slender, delicate structure; stem branched, bushy, erect; flowers small, greenish-yellow. Pods an inch long, numerous, erect, bearded. (Smith's Eng. Flor. vol. iii. p. 196.)

This is one of the plants which defeats the opinion that popular names are never imposed without good reason. The plant was formerly supposed to be a cure for fractured limbs, hence its name, Sophia chryseformis; an opinion only demonstrative of the contemptible state of surgery at the period when the name originated. Its medicinal powers as an antisyphilitic rest on equally mistaken observations.

The S. officinale is a naturalized foreigner in the United States. The indigenous species of this weed found in the States are, 1. The S. canadensis, or Hoary sisymbrium. 2. Arabis-like sisymbrium. 3. Thalian sisymbrium, commonly called Wall cress, Mouse-ear cress, extensively naturalized in the United States, in which 3 or 4 additional species of the plant are enumerated. (See Flor. Centric.)

HEDGE-KNIFE. Of this implement, for trimming hedges, there are two sizes, to be used either with one or both hands. The smaller one is a common and well-known implement. The larger-sized knife should have the blade 20 inches long by 2½ broad, and the handle 3 feet. It is slightly curved at the point.

HEDGE PARSLEY (Torsia). Of this useless weed there are in England three common species: the upright hedge parsley (T. authricens), the spreading hedge parsley (T. infesta), and the knotted hedge parsley (T. nodosum). They are annual plants, growing by waysides and the borders of fields, varying in height from 6 inches to 3 feet. The flowers are small, white or flesh-coloured, blowing in June; the umbels lateral and terminal; the rays from 7 to 10, rough, little spreading. Fruit small, purplish at the summit, furnished with incurved bristles. (Smith's Eng. Flor. vol. ii. p. 42.)

HELIOTROPE (Heliotropium; from helios, the sun, and trope, twining. The flowers are said to turn towards the sun). Some of the plants of this genus are highly valued for the fragrant perfume of their flowers, and are therefore to be met with in most gardens. They succeed freely in any rich, light soil; and cuttings of
HEMLOCK.

HEMLOCK (Conium maculatum). A herbaceous biennial plant distinguished for its poisonous qualities, very common in hedges, orchards, and waste ground, especially near towns and villages. The root is tape-shaped, whitish, and fleshy; from 6 to 12 inches long, not unlike a young parsnip.

HEMLOCK, THE WATER. See Cow-

BAY.

HEMLOCK, SPRUCE (Abies Canadensis). See Firs.

HEMP (Dan. hemp. Cannabis sativa). A very valuable plant of the nettle tribe, Urticaeae, which came, it is believed, originally from India, but has long since been naturalized in various parts of Europe. The chief cultivation is now, for the most part, confined to the Russian empire, where it is grown by the peasants in small plots. It there forms an article of export of very considerable commercial importance. Of 530,820 cwt.s of undressed hemp, imported into England in 1831, 506,803 came from Russia, 9472 from the East Indies, 7405 from Italy, 2262 from the Philippine islands, 2248 from the United States. (McCulloch.)

As Great Britain is principally dependent on other countries for a supply of hemp, it follows as a natural consequence, that, in periods of war, its price is very considerably increased.

The hemp plant is grown in some parts of Lincolnshire, Suffolk, and Norfolk, and in Ireland (where it reaches a height of 6 or 7 feet); but it is not nearly so much cultivated in the British islands as formerly, and it is believed by some of the best of the English farmers to be a crop that cannot be profitably grown in England, although the quality of the best British hemp is much superior to that of Russia.

In Oriental countries it sometimes attains a height of 16 to 18 feet. The hemp plant requires for its growth a fair, highly manured soil, but it is not particular as to the quality. Old deep meadow lands, all rich alluvial, and even peaty soils, are adapted to its growth. Its leaves are strongly narcotic, and in the eastern climates are used like opium, and smoked like tobacco. From its seeds (which are greedily devoured by birds) is extracted an oil, generally employed by painters.

The Russians and Poles, even of the higher classes, bruise or roast the seeds, mix them with salt, and eat them on bread. The hemp plant is fine and graceful; its tough and elastic fibres are adapted, above those of every other plant, for the making of cordage, canvass, netting, and various cloths, used in domestic economy, such as towels, and coarse table-cloths. Besides the strong cloth and other articles made from it, hemp is of considerable utility for other purposes. The refuse, called "hemp sheaves," affords an excellent fuel; and the fine oil, obtained from the seed, is peculiarly adapted for burning in chambers, as it is perfectly limpid, and possesses no smell.

Another valuable property of hemp is, that it effectually expels vermin from plantations of cabbages; if it be sown on the borders of fields, &c., planted with that vegetable, no caterpillar will infest it. (Willich's Donn. Ency.) It possesses the anomalous property of growing, without degenerating, for a series of years, on the same ground, provided the land is well manured. It is what is called a smothering-crop, for its copious foliage kills every thing that is attempted to be sown with it. It may be grown in the following rotation, as suggested by Professor Low.—1. Fallow; 2. Wheat; 3. Grasses; 4. Hemp; 5. Oats.

The land intended for hemp should be brought, by repeated ploughings, into a fine tilth. The seed may be sown in April and May, from two to three bushels per acre, either broadcast, and hoeing out the plants to a distance of 16 or 17 inches, or by the drill, at a distance of 30 inches. In the autumn, the plants are pulled, the male plants first, and the female plants six or seven weeks afterwards, when they have ripened their seed.

Thus there are two harvests of the hemp crop. The male plants are readily known by their unexpanded flowers, and yellowish colour. They are then tied in small bundles and carried to the pool, where they are to be steeped. Hemp, like flax, poisons the water in which it is steeped. The same process is followed when the female plants are pulled; only these, before they are steeped, have their seeds beaten out.

The process of steeping commonly lasts four or five days, and is continued until the outside coat of the hemp readily separates. It is then carefully and evenly spread on some grass turf, where it remains for three or four weeks, being turned over about twice every week, by which the decomposition of the woody part of the stem is materially accelerated. It is next carried to the barn, where it is bruised by the break, a machine constructed for the purpose; it is then bound up into bundles, and carried to market. (Louv's Pract. Agr. p. 348.)

There is a paper on a species of African hemp by Mr. A. Hunter (Trans. High. Soc. vol. iii. p. 87); others on the cultivation of hemp in America, by Mr. W. Thorne (Ann. of Agr. vol. xvii. p. 1); in Italy (ibid. vol. xvi. p. 439, and vol. ii. p. 216), and in Catalo-

nia. (Ibid. vol. viii. p. 243.) It seems that 100 parts of Indian hempsweed yield 20 to 25 per cent. of oil. (Conn. Agr. Asiat. Soc. 1838, p. 69.) See FLAX.

Hemp being an article of extensive utility, various plants have been tried as substitutes; among which are the Canada golden-rood (Solidago Canadensis), a perennial plant that might easily be cultivated in Britain; its stalks are numerous, straight, and grow above five feet in height; they afford very strong fibres, if treated in the same manner as hemp. The sun-flower (Helianthus) also affords single filaments or fibres, which are said to be as thick, and in all respects as strong, as small pack-thread. The fibrous stalk of the common nettle (Urceia dioica) has been advantageously manufactured into cloth. Others of the nettle tribe, such as the Chinese, or white-leaved nettle (U. nivea), and the Siberian, or hemp-leaved nettle (U. can-

nabina), yield tough and durable fibres; and the Syrian swallow-wort (Asclepias Syriaca) 19

HEMLOCK.

HEMP.
HEMP.

another of the textile plants; but no conclusively satisfactory experiments of their culture appear to have been made.

"Various common plants," says Professor Low (El. of Proc. Agr. p. 351), "yield fibres of sufficient toughness to be made into thread; as the Esparto-rush (Stipa tenacissima), which is used in Spain for obtaining coarse thread; the common broom (Cytisus scoparius); the Spanish broom (Spartium junceum); different species of aloe, and several plants of the lily tribe. The warmer regions of the world abound in plants possessing a fibrous structure of the bark, which renders them capable of being employed in making ropes, thread, and cloth." In Mexico and South America, the famous centennial American aloe (Agave americana), which there grows spontaneously, is extensively used in the manufacture of cordage of various kinds. There is no doubt that this plant would do well if introduced into the Florida Peninsula, as it even bears the winters at Charleston, South Carolina, and Augusta, Georgia. "If," says a correspondent of the Farmers Register, (vol. i. p. 6), "the same plant should be reared here, the greatest advantage would be gained by having at our disposal a vegetable silk as fine as the best silk, and a material for cordage as requisite or desirable in this country, we have in one a native plant, probably not inferior, for that purpose, to the Agave Americana."

I allude to the Yucca flamentosa, which grows spontaneously in light sandy soils, (and often on the very poorest) from Virginia to Florida, and is commonly known under the name of bear grass, and sometimes under that of silk grass. The fibres of this plant are remarkable for their strength, and I have seen ropes made of it equal in strength and appearance to any other. To obtain the fibres, the leaves are "rotted" in water, or by burying them in the earth. Mr. Elliot, in his Sketch of the Botany of South Carolina and Georgia, says of this plant, that it appears to possess the strongest fibres of any vegetable whatever; and, if it can be raised with facility, may form a valuable article in domestic economy. The root is also a substitute for soap in washing woollens.

"Of the facility of its production, I entertain no doubt. No plant is more hardy, or bears transplanting better. Its roots are extensive, having numerous eyes, or buds, and each one of these will produce a plant. There are millions of acres in the Southern States unfit for the ordinary purposes of agriculture, which would produce this plant very well." In the Western United States, and especially in the upper part of Kentucky, hemp is extensively cultivated, and constitutes a staple crop. A very interesting communication was made a few years since to the "Western Agriculturist," upon the mode of conducting the various processes connected with the hemp culture in Kentucky, by the distinguished statesman and agriculturist, Mr. Clay. The correctness of his views and recommendations are fully confirmed by those who have put them to the test of experience; and as the subject is one of great agricultural importance, we shall extract nearly the whole of Mr. Clay's essay.

Though raised in other parts of the state of Kentucky, hemp is most extensively cultivated in the Elkhorn region around and near Lexington.

HEMP.

The soil of that region, says Mr. Clay, is a rich, deep, vegetable loam, free from sand and with but little grit. It lies on a bed of clay, interspersed with small fragments of iron ore, and this clay in its turn reposes on a mass of limestone lying many feet in depth in horizontal strata. The surface of the country is generally undulating. The rich land (and there is but little that is not rich), in this whole region, is well adapted to the growth of hemp, where it has not been too much exhausted by injudicious tillage. The lands which produce it best, are those which are fresh, or which have lain the meadow grass or clover. Management is not yet much practised. Clover is used in lieu of it. Lands which remain in clover four or five years without being too constantly and closely grazed, recover their virgin fertility. The character of the soil in the other parts does not vary materially from that in the Elkhorn district.

The preparation of the ground, for sowing the seed, is by the plough and horses, until the clods are sufficiently pulverized or dissolved, and the surface is made smooth and level. It should be as carefully prepared as if it were for flax. This most important point, too often neglected, cannot be attended to too much. Scarcely any other crop better rewards diligence and careful husbandry. Fall or winter ploughing is practised with advantage—it is indispensable in old meadows, or old pasture-grounds intended for producing hemp. Plants for seed are ordinarily reared, in a place distinct from that in which they are cultivated for the fibre. The mode is different from that which is understood to prevail in Europe. The seeds which are intended to reproduce seeds for the crop of the next year, are sowed in drills about four feet apart. When they are grown sufficiently to distinguish between the male and female stalks, the former are pulled and thrown away, and the latter are thinned, leaving the stalks separated seven or eight inches from each other. This operation is usually performed in the blooming season, when the sexual character of the plants is easily discernible: the male alone blossoms, and, when agitated, throwing off farina, a yellow dust, or flour which falls and covers the ground, or any object that comes in contact with it. A few of the male plants had better be left, scattered through the drill, until the farina is completely discharged, for an obvious reason. Between the drills a plough is run sufficiently often to keep the ground free from weeds and grass; and between the stalks in each drill the hoe is employed for the same object. The seed plants are generally cut after the first smart frost, between the 25th September and the middle of October, and carried to a barn or stackyard, where the seeds are easily detached by the common thrail. They should be gathered after a slight, but before a severe frost; and, as they fall out very easily, it is advisable to haul the plants on a sled, and, if convenient, when they are wet. If transported on a cart or wagon, a sheet should be spread to catch the seed as they shatter out. After the seeds are separated, the stalks which bore them being too large, course, and harsh, 614
HEMP.

to produce lint, are usually thrown away; they may be profitably employed in making charcoal for the use of powder-mills. In Europe, where the male and female plants are promiscuously grown together in the same field, both for seeds and for lint, the male stalks are first gathered, and the female suffered to remain growing until the seeds are ripe, when they are also gathered, the seeds secured and lint obtained, after the roting, from both descriptions.

After the seeds are threshed out, it is advisable to spread them on a floor to cure properly and prevent their roting, before they are finally put away for use the next spring. Seeds are not generally used, unless they were secured the fall previous to their being sown, as it is believed they will not vegetate, if older; but it has been ascertained that, when they are properly cured and kept dry, they will come up after the first year. It is important to prevent them from heating, which destroys the vegetative power of the black seed, and for that purpose they should be thinly spread on a sheltered floor.

The seeds—whether to reproduce seeds only, or the lint—are sowed about the same time. Opinions vary as to the best period. It depends a good deal upon the season. The plant is very tender when it first shoots up, and is affected by frost. Some have sowed as early as the 1st of April; but it is generally agreed, that all the month of May, and about the 10th of it especially, is the most favourable time. An experienced and successful hemp-grower, in the neighbourhood of Lexington, being asked the best time to sow hemp, answered immediately before a rain.—And undoubtedly it is very fortunate to have a moderate rain directly after sowing.

"Would it not be well to soak the seed in water a few hours previous to sowing! We have found this to answer nearly as good a purpose as rain after sowing, with all seeds with which we have tried it. The vegetation of mangle-wurzel is wonderfully accelerated by it."—Ed. Am. Farmer.

When the object is to make a crop of hemp, the seeds are sown broadcast. The usual quantity is a bushel and a half to the acre; but here again the farmers differ, some using two bushels or even two and a half. Much depends on the strength and fertility of the soil, and the care with which it has been prepared, as well as the season. To these causes may be ascribed the diversity of opinion and practice. The ground can only sustain and nourish a certain quantity of plants; and if that limit be passed, the surplus will be smothered in the growth. When the seeds are sown, they are ploughed or harrowed in; ploughing is best in old ground, as it avoids the injurious effect of a beating rain, and the consequent baking of the earth. It would be also beneficial, subsequently to roll the ground with a heavy roller.

After the seeds are sown, the labours of the cultivator are suspended, until the plants are ripe, and in a state to be gathered—everything in the intermediate time being left to the operations of nature. If the season be favourable until the plants are sufficiently high to shade the ground (which they will do in a few weeks, at six or eight inches height,) there is a strong probability of a good crop. When they attain that height, but few articles sustain the effect of bad seasons better than hemp.

It is generally ripe and ready to be gathered about the middle of August, varying according to the time of sowing. Some sow at different periods, in order that the crop may not all ripen at the same time, and that a press of labour, in reaping it, may be thus avoided. The maturity of the plant is determined, by the evaporation of the farina, already noticed, and the leaves of the plant exhibiting a yellowish hue: it is then generally supposed to be ripe, but it is safest to wait a few days longer. Very little attentive observation will enable any one to judge when it is fully ripe. In that respect it is a very accommodating crop: for if gathered a little too soon, the lint is not materially injured, and it will wait the leisure of the farmer some 10 days or a fortnight after it is entirely ripe.

Two modes of gathering the plants are practised; one by pulling them up by the roots, an easy operation with an able-bodied man, and the other by cutting them about two inches (the nearer the better) above the surface of the ground. Each mode has its partisans, and I have pursued both. From a quarter to a third of an acre, is the common task of an average labourer, whether the one or the other mode is practised. The objections to pulling are, that the plants with their roots remaining connected with them, are not afterwards so easily handled in the several operations which they must undergo; that all parts of the plant do not rot equally and alike, when exposed to the dew and rain; and, finally, that before you put them to the brake, when the root should be separated from the stalk, the root hangs off with it some of the lint. The objection to cutting is, that you lose two or three inches of the best part of the plant nearest the root. Pulling, being the most ancient method, is most generally practised. I prefer upon the whole, cutting—and I believe the number who prefer it is yearly increasing. When pulled, it is done with the hand, which is better for the protection of an old leather glove. The labourer catches 20 or 30 plants together, with both hands, and, by a sudden jerk, draws them without much difficulty. The operation of cutting is performed with a knife, often made out of an old scythe, resembling a sickle, though not so long, but broader. This knife is applied much in the same way as the sickle, except that the labourer stands more.

Whether pulled or cut, the plants are carefully laid on the ground, the evener the better, to cure—which they do in two or three days, in dry weather. A light rain falling on them whilst lying down is thought by some to be beneficial, inasmuch as the leaves, of which they should be deprived, may be then easier shaken off or detached. When cured, the plants are set up in the field in which they were produced, in shocks of convenient size, the roots and butt-ends resting on the ground, and the tops united above by a band made of the plants themselves. Previous to putting them up in shocks, most cultivators tie the
plants in small hand-bundles of such a size as that each can be conveniently held in one hand. Before the shocks are formed, the leaves of the plants should be rapidly knocked off with a rough paddle or hooked stick. Some suffer the plants to remain in these shocks until the plants are spread down to be rotted. Others, again, collect the shocks together as soon as they can command leisure (and it is clearly best), and form them into stacks. A few farmers permit these stacks to remain over a whole year, before the plants are exposed to be rotted. But I have frequently done it with advantage, and have at this time two crops in stalks. By remaining that period in stacks, the plants go through a sweat, or some other process that improves very much the appearance, and, I believe, the quality of the lint, and this improvement fully compensates the loss of time in bringing it to market. The lint has a soft texture and a lively hue, resembling water-rotted hemp; and I once sold a box of it in the Baltimore market at the price of Russian hemp. In every other respect, the plants are treated as if they were not kept over a year.

The method of dew-rotting is that which is generally practised in Kentucky. The lint so spread is not so good for many purposes, and especially for rigging and ships, as when the plants have been rotted by immersion in water, or, as it is generally termed, water-rotted. The greater value, and consequently higher price, of the article, prepared in the latter way, has induced more and more of our farmers every year to adopt it; and, if that prejudice were subdued, which every American production unfortunately encounters, when it is first introduced and comes in competition with a rival European commodity, I think it probable that, in a few years, we should be able to dispense altogether with foreign hemp. The obstacles, which prevent the general practice of water-rotting, are, the want of water at the best season for the operation, which is the month of September; a repugnance to the change of an old habit; and a persuasion which has some foundation, that handling the plants, after their submersion in water during that month is injurious to health. The first and last of these obstacles would be removed by water-rotting early in the winter, or in the spring. The only difference in the operation, performed at those seasons and in the month of September, would be, that the plants would have to remain longer in soak before they were sufficiently rotted.

The plants are usually spread down to be dew-rotted, from the middle of October to the middle of December. A farmer who has a large crop on hand, puts them down at different times for his convenience in handling and dressing them. Autumnal rottng is more apt to give the lint a dark and unsightly colour than winter-rotting. The best ground to expose the plants upon is meadow or grass-land, but they are not infrequently spread over the same field on which they grew. The length of time they ought to remain exposed, depends upon the degree of moisture and the temperature of the weather that prevail. In a very wet and warm spell five or six weeks may be long enough. Whether they have been sufficiently rotted or not is determined by experiment. A handful is taken and broken by the hand or applied to the brake, when it can be easily ascertained, by the facility with which the lint can be detached from the stalk, if it be properly rotted. If the plants remain on the ground too long, the fibres lose some of their strength, though a few days longer than necessary, in cold weather, will not do any injury. If they are taken up too soon, that is before the lint can be easily separated from the woody part of the stalk, it is harsh, and the process of breaking is difficult and troublesome. Snow-rotting, that is when the plants, being spread out, remain long enough to rot (which however requires a greater length of time), bleaches the lint, improves the quality, and makes it nearly as valuable as if it had been water-rotted.

After the operation of rottng is performed, the plants are again collected together, put in shocks or stacks, or which is still better, put under a shed or some covering. When it is designed to break and dress them immediately, they are frequently set up against some neighbouring fence. The best period for breaking and dressing is in the month of February and March, and the best sort of weather, frosty nights and clear thawing days. The brake cannot be used advantageously in wet or moist weather. It is almost invariably used in this state out of doors, and without any cover, and to assist its operation, the lone manner that a large fire near it, which serves the double purpose of drying the plants and warming himself. It could not be used in damp weather in a house without a kiln or some other means of drying the stalks.

The brake in general use is the same hand-brake which was originally introduced, and has been always employed here, resembling, though longer than the common flap-brake. It is so well known as to render it unnecessary to give a description of it, perhaps, unnecessary. It is a rough contrivance, set upon four legs, about two and a half feet high. The brake consists of two jaws with slits in each, the lower jaw fixed and immovable, and the upper one movable, so that it may be lifted up by means of a handle inserted into a head or block at the front end of it. The lower jaw has three slats or teeth made of tough white oak, and the upper two, arranged approaching to about two inches in length, and in such manner that the slats of the upper jaw play between those of the lower. These slats are about six or seven feet in length, six inches in depth, and about two inches in thickness in their lower edges; they are placed edgeways, rounded a little on their upper edges, which are sharper than those below. The labourer takes his stand by the side of the brake, and grasping in his left hand as many of the stalks as he can conveniently hold, with his right hand he seizes the handle in the head of the upper jaw, which he lifts, and, throwing the handful of stalks between the jaws, repeatedly strikes them by lifting and throwing down the upper jaw. These successive strokes break the woody or
HEMP.

reddy part of the stalks into small pieces or shoes, which fall off during the process. He assists their disengagement by striking the handful against a stake, or with a small wooden paddle, until the lint or bark is entirely clean, and completely separated from the woody particles.

After the above operation is performed, the hemp may be scutched to soften it, and to strengthen the threads. That process, however, is not thought to be profitable, and is not therefore generally performed by the grower, but is left to the manufacturer, as well as that of beating and heckling it. Scutching is done by the labourer taking in his left hand a handful of lint, and grasping it firmly, then laying the middle of it upon a semi-circular notch of a perpendicular board of the scutching-frame, and striking with the edge of the scutch that part of the lint which hangs down on the board. After giving it repeated strokes, he shakes the handful of lint, replaces it on a notch, and continues the process until all parts of it, until it is sufficiently cleansed, and the fibres appear to be even and straight.

The usual daily task of an able-bodied hand at the brake is 80 pounds' weight, but there is a great difference not only in the state of the weather, and the condition of the stalks, produced by the greater or less degree in which they have been rotted, but in the dexterity with which the brake is employed. Some hands have been known to brake from 150 to 200 pounds per day. The labourer ties up in one common bundle the work of one day, and in this state it is taken to market and sold. From what has been mentioned, it may be inferred, as the fact is, that the hemp of some growers is in a much better condition than that of others. When it has been carelessly handled or not sufficiently cleansed, a deduction is made from the price by the purchaser. It is chiefly bought in our villages, and manufactured into cotton-bagging, bales, and other kinds of untaurled cordage. The price is not uniform. The extremes have been as low as three, and as high as eight dollars, for the long hundred—the customary mode of selling it. The most general price during a term of many years, has been from four to five dollars. At five dollars it compensates well the labour of the grower, and is considered more profitable than any thing else the farmer has cultivated.

The most heavy labour in the culture of hemp, is pulling or cutting it, when ripe, and breaking it. This labour can easily be performed by men. Various attempts have been made to improve the process of breaking, which is the severest work in the preparation of hemp. A newly invented machine was erected for that purpose on my farm six or eight years ago, to dress hemp by dispensing with rotted altogether, similar in structure to one which was exhibited about the same time at Columbus, during the sitting of the Ohio legislature. It was worked by horse power, and detached the lint tolerably well, producing a very fine looking up, resembling in appearance Russia hemp. A ton of it was sold to the navy department, which was manufactured into rigging for the ship of the line, the North Carolina, prior to her making a voyage of three years in the Mediterranean. Upon her return, the cordage was examined and analyzed; and although its exterior looked very well, it was found, on opening it, to be decayed and affected somewhat like the dry-rot in wood. I considered the experiment decisive; and it is now believed that the process of water or dew-rotting is absolutely necessary, either before or after the hemp has been to the brake. There is a sappy or glutinous property in which it is rich, which can not be removed by the only process that has been hitherto generally and successfully employed to divest it.

An ingenious and enterprising gentleman in the neighbourhood of Lexington, has been, ever since the erection of the above-mentioned machine, trying various experiments, by altering and improving it, to produce one more perfect, which might be beneficially employed on rotted hemp, to diminish the labours of the brake. He mentioned the other day that all of them had been before that he had returned to the old hand-brake, and that he was convinced that it answered the purpose better than any substitute with which he was acquainted. I observe Mr. H. L. Barnum has recently advertised a machine, which he has constructed for braking and dressing hemp and flax, which can be procured at the establishment of Mr. Smith, in Cincinnati. I most cordially wish him success; but the number of failures which I have witnessed, during a period of 30 years, in the attempts to supersede manual labour by the substitution of that of machines, induces me to fear that it will be long before this desideratum is attained.

The quantity of net hemp produced to the acre, is from 600 to 1000 weight, varying according to the fertility and preparation of the soil and the state of the season. It is said that the quantity which any field will produce, may be anticipated by the average height of the plants throughout the field. Thus—if the plants will average eight feet in height, the acre will yield 800 pounds of hemp, of the length corresponding to a hundredweight of the lint.

Hemp exhausts the soil slowly, if at all. An old and successful cultivator told me that he had taken 13 or 14 successive crops from the same field, and that the last was the best. That was probably, however, owing to a concurrence of favourable circumstances. Nothing cleanses and prepares the earth better for other crops (especially for small grain or grasses) than hemp. It eradicates all weeds, and when it is taken off, leaves the field not only clean, but smooth and even.

The rich lands of Ohio, Indiana, and Illinois, are, I have no doubt, generally well adapted to the cultivation of this valuable plant; and those states enjoy some advantages for the cultivation of it, which this does not possess. Their streams do not dry up as much as ours, and they consequently employ better than we can, the agency of water, in the preparation of it. Their projected canals, when completed, will admit of its being carried to the Atlantic capitals at less expense in the transportation than we can send it. (American Farmer, vol. iv.)
HENBIT.

Mr. Ellsworth, in his report upon improvements in agriculture, &c., made in the United States, in 1842, observes in relation to the hemp culture, that attention is still directed, and it would seem with somewhat more success, to the discovery of a process of water-rotting hemp; and it is hoped that the difficulties on this subject may yet be removed. It is stated that, in consequence of the promise of the last winter of sending out a government agent to purchase water-rotted hemp for the navy, the farmers of Kentucky and Missouri have water-rotted 700 tons or more. This, at the prices paid by the government for Russian hemp, is worth $200,000. Many specimens, it is further stated, have been examined, and pronounced equal to Russia hemp. Were a suitable reward to be offered, to stimulate the ingenious, it can hardly be doubted that, by a variety of experiments, some process of preparing it for the use of the navy, as well as the Russia hemp, might be found out.

An important discovery, respecting the application of waste hemp to the purpose of paper-making, has recently been announced; and if, when it is sufficiently tested, it proves all that it promises, it will afford an additional inducement to the culture of hemp. A process is said to have been found out, by which hemp can be made white as snow, and that it can be used in manufacturing the finest and whitest paper; and a belief is entertained that hemp waste, which can be furnished at two cents per pound, will ere long be sought for by paper-makers, to supply the place of linen rags.

Hemp is beginning to be raised somewhat more in the Northern and Eastern States. This is true especially of the northern part of the state of New York. At present, however, it is confined to the seed crop, owing to the high price of the seed. It is affirmed to be a mistake to suppose that it must be confined to alluvial lands, as has been shown by the farmers of Saratoga and Washington counties, in the state of New York. We import hemp or hempen articles, some years, to the extent of $9,000,000 or $10,000,000 in value. It is worth from $200 and upwards per ton. When planted in drills, at a suitable distance, as it should be, and properly cultivated, hemp generally produces from 20 to 40 bushels of seed to the acre; and instances are not rare of its yielding from 50 to 60. The seed is generally worth from 3 to 6 dollars per bushel. When sown for the lint, it should be sown broadcast, from 2 to 3 bushels of seed to the acre, depending on the quality of the land; and it usually produces from 700 to 1000 weight of clean hemp to the acre. Much valuable information respecting the culture and importance of this crop may be found in the files of the Kentucky Farmer for the last few years.

HEMP AGRIMONY (Eupatorium cannabinum). A rough perennial herb, growing in England in watery, boggy places, especially about the banks of rivers, with a tufted, somewhat creeping root, with many long fibres. Stems several, 2 or 3 feet high, branched, downy, often brown or purplish, filled with pith. Leaves on short stalks, deep green, downy, but rather rough to the touch. The flowers form dense, pale, purplish corymbose tufts, at the top of the stem and upper branches. The whole herb is slightly aromatic. Some species of agrimony are used in gargles, and as tea. See Agrimony. (Smith's Eng. Flor. vol. iii. p. 490.)

HEMP, INDIAN (Apocynum cannabinum). An American plant with a perennial root, found in the borders of woodlands and other situations in the Middle States, flowering in August. The stems grow from 2 to 4 feet high, smooth, purple, slightly glaucous, with rather erect branches. The leaves are from 2 to 4 or 5 inches long, half an inch to an inch and a half wide, elliptic in general form, and more or less downy beneath. The greenish-white flowers are numerous, and sometimes tinged with red. There seems to be several varieties referable to this species, the bark of which affords a strong fibre similar to that of hemp. One or two additional species of apocynum have been met with in the United States. (Flora Cestricea.)

1. Red hemp-nettle (G. luteum).
2. Downy hemp-nettle (G. villina).

HENBANE (Hyoscyamus niger). Black henbane. This annual herb abounds about villages, road-sides, and among rubbish, and in England flowers in July. Neither horses, cattle, swine, nor sheep, will touch this plant, and it is not relished by goats. The whole plant is fatal to poultry, whence its common name. It is nauseous to hogs, but not to swine, cows, or dogs, and goats are able to bear a tolerable proportion before they are affected. The leaves are active only in the second year of the plant: if scattered about buildings, they are said to drive away mice and rats. If more than a small portion of the leaves should have been accidentally swallowed, brisk emetics ought instantly to be taken; and after discharging the contents of the stomach, it will be necessary to administer some mild drinks, such as large portions of vinegar, or lemon juice diluted with water, as the stomach is able to support them.

Henbane owes its medicinal properties to an alkali, hyoscyamine, which can be obtained in a separate state. It is crystallizable. Besides this alkali, the plant yields by destructive distillation an empyreumatic oil, which is a powerful narcotic poison. Notwithstanding these virulent properties, henbane has been professionally administered with considerable success in many obstinate diseases. The expressed juice of the leaves, evaporated to the consistency of extract, has long been used as a narcotic, an anti-spasmodic, and a soporific.

HENBIT, THE GREAT, or Henbit DEAD NETTLE. See Dead Nettle. In England
Plate 9.

Inferior Herbage plants occasionally cultivated.
HENBIT.

HENBIT, SMALL. See Speedwell.

HEPATICA, or LIVERWORT (Asimone hepatica). Miller mentions five sorts: the single blue (nobilis), the double blue (plena), the single white (alba), the single red (vulgaria), and the double red (rubra). In England these beautiful and early perennial produce their flowers in February and March, before any leaf appears. The double sorts remain longer in flower than the single ones. The single flowers produce seed every year; the seed should be sown in pots or boxes of light earth in August, to receive only the morning sun till October, when the plants must be placed in as sunny a spot as possible through the winter. The seedlings may be transplanted the following August into the borders, and left there undisturbed. Hepaticas do not bear transplanting well; and the roots should only be parted once in three or four years. The hepatica loves an eastern aspect, and a loamy soil. They are three years before they flower handsomely. See Liverwort.

HERBAL (Lat. herbarium). A collection of dried plants, such as the old botanists termed a hortus siccus or dry garden. It is also applied to books which contain a methodical arrangement of the classes, genera, species, and varieties of plants, together with an account of their properties. Dry herbals are formed by gluing to sheets of paper, twigs and other parts of plants pressed flat, and dried in bibulous paper or otherwise. If well prepared, they are as useful to the botanist as living plants; but it is necessary to have some practical skill to be able to employ them advantageously. The best method of making a hortus siccus or herbal, is to place the plant to be dried between paper of a soft and spongy, unglazed texture, under a slight pressure. On the following day the plant should be spread in as natural a form as possible, between folds of fresh, dry, blotting paper; and a pressure greater than before employed. In a week it will be sufficiently dry for pasting on a half sheet of white paper; to which the name of the plant, its habitat, and the natural order, with the date, may be appended. The largest public herbaria are those of the museum at Paris, the imperial collection at Vienna, the royal of Berlin, and that of the British museum, London, formerly Sir Joseph Banks's. Nothing certain is known of the extent of these collections, but they probably contain in some cases as many as 60,000 species. The herbarium is not an attractive part of public museums; but a very important one for numerous purposes of science, both practical and speculative. (Brandes Dict. of Science.)

HERBIVEROUS ANIMALS, FOOD OF. M. Dumas, in a paper recently read before the French Academy, states, that he has ascertained the quantity of fat in animals in a healthy state does not depend on some peculiar process in the digestion, but upon the quantity of fatty matter contained in the food eaten. He states, that, on analysis of hay and Indian corn or maize, he found the former yield 2 per cent. of fatty matter and the latter 9 per cent. Herbiverons animals, he says, always make less fat than the amount of fat contained in their food; but the milch cow furnishes a larger quantity than any other animal, and the quantity of butter that she supplies, would, if weighed, be found equivalent to that contained in her food.

HERD (Sax. hirde). A number of beasts congregated together. It is particularly applied to black cattle. Herd or herdsman also sufficiently signifies a keeper of cattle, and in the north of England it is still used.

HERD'S GRASS, or Foul Meadow Grass. This grass is a spontaneous growth, says Buel, of the wet lands of the United States. The white top and red top are different varieties of herd's grass.

HERRING (Clupea harengus). This well-known fish is found in great abundance from the highest northern latitudes down to the northern coast of France. Large shoals of them frequent the coasts of the British Islands, and give employment to a considerable number of boats and men, forming a principal article of commerce. A very elaborate treatise on the natural history and the different modes of fishing and curing the herring, by Mr. John Mitchell, was published in the Edin. Quart. Journ. of Agr., vol. x. p. 1.

The scales and other refuse of the herring fishery of the Suffolk coast are used with great success as manure by the farmers in the neighbourhood of Lowestoff. There is no doubt that this fish is a powerful manure. The cake produced in Sweden by the herring oil-makers is considered by the farmers of that cold country to be the most powerful of fertilizers. And I have in another place given the result of an experiment with some spoiled dried herrings on a Kentish hop plantation. (Johnson on Salt, p. 101; Trans. High. Soc. vol. v. p. 404.) See Fish, as a Manure.

Most of the varieties of herring found in Europe have been recognised on the Atlantic coast of the United States. The manihaden, caught in such numbers on the shores of Long Island Sound, and there used so extensively and profitably as manure, belongs to the herring family (Clupea manihaden).

HESSIAN FLY. See Fly in Wheat.

HICKORY. A common name throughout the United States, applied to several species of the walnut genus, which, in the variety of trees composing the vast original forests east of the Mississippi, ranks after the oak in the number of its species. The botanical section which includes the hickories, according to Michaux's arrangement, contains eight species; namely Pycnanthem Hickory, Bitternut Hickory, Water Bit

619
HICKORY.

ternut Hickory, Mockernut Hickory, Shellbark Hickory, Thick Shellbark Hickory, Pignut Hickory, and Nutmeg Hickory. The three first-named species bear the nearest relation with the black walnut and butternut, their buds not being covered with scales.

The various species of hickory differ very greatly from the black walnut and butternut in the properties of their wood. The general form and foliage of hickories, also, bear a striking resemblance, though they differ in the number and size of their leaflets. The fruit often varies greatly in appearance. All the species of hickory, together with the black walnut and butternut, comprise an indigenous genus, no species of which is met with in Europe, or any other part of the old world.

1. Pecanenut Hickory (Juglans oteiformis of Michaux; Carya angustifolia and Juglans angustifolia of other naturalists). This species, which, says Michaux, is found in Upper Louisiana and Illinois, is called by the French Pecanier, and its fruit Pecanes. On the borders of the rivers Missouri, Illinois, St. Francis, and Arkansas, it is most abundantly multiplied. It is also common on the Wabash, and on the Ohio is found for 200 miles from its junction with the Mississippi. Higher than this it becomes more rare, and is not seen beyond Louisville. This tree is partial to cold, wet grounds. On the right bank of the Ohio, opposite the river Cumber-land, there is a swamp of 800 acres, which is said to be entirely covered with it.

The Pecanenut is a beautiful tree, with a straight and well-shaped trunk, attaining in the forests the height of 60 or 70 feet. Its wood is coarse-grained, and, like that of other hickories, heavy and compact, possessing great strength and durability, though in this last respect not equal to some other species. The nuts, which are usually abundant, are contained in a husk from one to two lines thick, and have four slightly prominent angles, corresponding to their internal divisions. They vary in length from an inch to an inch and a half, are pointed at the extremities, of a cylindrical form, and of a yellowish colour, marked, at the period of perfect maturity, with blackish or purple lines. The shell is smooth and thin, though too hard to be broken by the fingers; the kernel is full, and, not being divided by ligneous partitions, is easily extracted. These nuts, which are of a very agreeable taste, form an object of petty commerce between Upper and Lower Louisiana. From New Orleans they are exported to the West Indies and to the ports of the United States. They are not only better than any other species of North American walnuts, but they appear to be even more delicately flavoured than those of Europe. And, besides, varieties of the pecanenut are found whose fruit is far superior to that of the European walnut unimproved by culture. This tree therefore merits the attention of both Americans and Europeans, that by assiduous cultivation it may be brought to the highest degree of perfection. These advantages, it is true, are balanced in part by the slowness of its growth; there are trees in France which have been planted more than thirty years, and which do not yield fruit.

If the practice should be successfully adopted of grafting the pecanenut on the black walnut, or on the common walnut, its vegetation would be incomparably more rapid, and no motive would discourage its propagation in Europe.

2. Bitternut Hickory (Juglans anamara). This tree is also called in Lancaster county and some other parts of Pennsylvania, and the Middle States by the names of White Hickory and Swamp Hickory, the latter name being derived from its frequently flourishing on the rich alluvium found in swamps and on the banks of rivers subject to overflowing. Further south it is confounded with the Pignut hickory. Its vegetation is more hardy than that of other hickories.

The Bitternut hickory, Michaux informs us, is nowhere found much beyond the boundaries of Vermont in the latitude of 45°. "The fruit is ripe about the beginning of October; it is so plentiful that several bushels are sometimes gathered from a single tree. The husk is thin, fleshy, and surmounted on its upper half by four appendages in the form of wings. It never becomes ligneous like those of the other hickories, but softens and decays. The form of the nut in this species is more constant and more regular than in the others. It is broader than it is long, being 6 or 7 lines one way and 10 lines the other. The shell is white, smooth, and thin enough to be broken by the fingers. The kernel is remarkable for the deep inequalities produced on every side by its foldings. It is so harsh and bitter that squirrels and other wild animals will not feed on it while any other nut is to be found.

"In some parts of Pennsylvania, where this tree is multiplied, an oil is extracted from the nuts, which is used for the lamp and for other inferior purposes. But from these experiments, in which individuals have succeeded, it is not to be concluded that a sufficient product of this sort can be obtained to form a branch of industry.

3. Water Bitternut Hickory (Juglans aquatica). "N0 specific name," says Michaux, "has hitherto been given to this species, which is confined to the Southern States; it is confounded with the Pignut hickory, though differing from it in many respects. The name which I propose appears sufficiently appropriate, for I have always found this tree in swamps, and in the ditches which surround the rice fields, where it is accompanied by the red-flowering maple, Tupelo, cypress, and Carolina poplar. The Water Bitternut hickory grows to the height of 40 or 50 feet, and in its general appearance resembles the other hickories. Its leaves are 8 or 9 inches long, and of a beautiful green. They are composed of 4 or 5 pair of sessile leaflets, surmounted by a petiolated odd one. The leaflets are serrate, 4 or 5 inches long, 8 or 9 lines broad, and very similar to the leaves of the peach tree.

"The husk is thin, and the nuts are small, angular, a little depressed at the sides, somewhat rough, of a reddish colour, and very tender. The kernel is formed in folds like that of the Bitternut hickory: as may be supposed,
HICKORY.  

it is not eatable. The wood of this species, though partaking of the common properties of the hickories, is in every respect inferior to the others, from the nature of the grounds on which it grows.

4. Mockernut Hickory (Carya tomentosa of other naturalists), Common hickory. "In the parts of New Jersey which lie on the river Hudson, and in the city of New York and its vicinity, this species," says Michaux, "is known by the name of the Mockernut hickory, and less commonly of White-heart hickory; at Philadelphia and Baltimore, and in Virginia, that of Common hickory is the only one in use. The French of Illinois call it Noyer dor, or Hard walnut. The first of these denominations, which is descriptive of the fruit, I have for that reason adopted.

"This species is not, as the name which it bears in that country would indicate, more multiplied in Pennsylvania, and further south, than the other hickories. I have not seen it north of Portsmouth in New Hampshire, though 100 miles south, in the neighbourhood of Boston and Providence, it is common. It is most abundant in the forests that still remain on the coast of the Middle States, and in those which cover the upper parts of the Carolinas and of Georgia; but in the last mentioned states it becomes more rare in approaching the sea, as the sterility of the soil, in general dry and sandy, is unpropitious to its growth. I have noticed, however, that this is the only hickory which springs in the pine barrens; the sprouts are burnt every year, and never rise higher than 3 or 4 feet. I have made the same observations in traversing the Big barrens of Kentucky and Tennessee, where the Mockernut hickory and Black Jack oak alone are seen. They survive the conflagrations which almost every spring envelope the prairies, but their vegetation is checked by the fire, and they do not exceed the height of 8 or 10 feet.

"Like most of the walnuts, the Mockernut hickory flourishes in rich soils, and chiefly on the gentle aceliares which surround the swamps, where it grows, mingled with the sweet gum, poplar, sugar maple, bitternut hickory, and black walnut. In these situations it reaches its greatest size, which is commonly about 60 feet in height, and 18 or 20 inches in diameter. I remember to have seen larger Mockernut hickories near Lexington, in Kentucky, but this extraordinary growth in several species of trees is rarely seen on this side of the Alleghanies, and is attributable to the extreme fertility of the soil in the Western country. Of all the hickories, however, the Mockernut succeeds best on lands of a middling quality; for it forms a part of the waste and impoverished forests which cover the meager, sandy soil of Lower Virginia; though under these disadvantages it exhibits but a mean and stunted appearance.

"The buds of this species are large, short, of a grayish white, and very hard; in the winter, after the falling of the leaf, they afford the only characteristic by which the tree can be distinguished, when it exceeds 8 or 10 feet in height.

"The fruit is ripe about the 16th of November. It is odorous, sessile, or rarely pendunculated, and commonly united in pairs. In form and size it exhibits remarkable varieties: on some trees it is round, with depressed seams; on others oblong, with angular or prominent seams; 2 inches long and 12 or 15 lines in diameter, and sometimes of less than half this size. The shell is very thick, somewhat channelled, and extremely hard. The kernel is sweet, but minute, and difficult to extract, on account of the strong partitions which divide it: hence, probably, is derived the name of Mockernut, and hence, also, this fruit is rarely seen in the markets.

"Of all the hickories this species is of the slowest growth: a fact which I have proved by planting nuts of the several species, and by comparing the length of their annual shoots. I have also been led to believe that it is the most liable to be attacked by worms, and especially by the Callidium felosanum, whose larva eats within the body of the tree. These considerations appear sufficiently weighty to induce cultivators, in forming large plantations, to prefer some other species which are described in the sequel."

5. Small-fruited Hickory (Carya microcarpa of Nuttall and Darlington, Juglans compressa of Muhlenburg, and J. alba nutata of Battand Hickory of Marshall.) This species is allied to the Carya tomentosa or Common hickory. Nuttall informs us that he first observed it on the banks of the Schuylkill, in the vicinity of Philadelphia, and Dr. Darlington remarks that it is frequent in moist woodlands in Chester county, Penn. The nut is of nearly the same form as that of the Common hickory, has a thin shell, pleasant taste, but is quite small, seldom exceeding the size of a nutmeg. These peculiar nuts grow in Massachusetts. The species is remarkable for the smoothness of its leaflets, which in this respect, says Nuttall, resemble those of the Carya glabra or Pignut, but they are larger and less deeply serrated.

6. Shellbark Hickory (Juglans aquamosa of Michaux, and Carya alba of Darlington and other botanists). The singular disposition of the bark in this species has given rise to the descriptive names of Shellbark, Shagbark, and Scaly-bark hickory, the first of which is in most general use in the Middle and Southern States. Many descendants of the Dutch settlers, says Michaux, call it Kisky Thomas nut. It is not found further north than Portsmouth, New Hampshire, where its stature is stunted by the rigours of the climate. "It abounds on the shores of Lake Erie, about Geneva in Genesee, along the Mohawk river, in the neighbourhood of Goshen in New Jersey, and on the banks of the Susquehanna and Schuylkill rivers in Pennsylvania. In Maryland, in the lower parts of Virginia, and in the other Southern States it is less common. In South Carolina I have not noticed it nearer Charleston than the parish of Goose-Creek, about 24 miles distant. It is met with in the Western States, but not as frequently as the following species, the Thicken Shellbark hickory, to which it bears a striking analogy, and with which it is crowned by the inhabitants. East of the Alle.
HICKORY.

The fruit of the Shellbark hickory is ripe about the beginning of October. Some years it is so abundant that several bushels may be gathered from a single tree. It varies in size according to the soil and the exposure in which it is produced, but 5 inches may be assumed as the average of its circumference. The shape is uniformly round, with four depressed seams, in which the husk opens at the season of perfect maturity, dividing itself completely into equal sections. The entire separation of the husk, and its thickness disproportioned to the size of the nut, form a character peculiar to the Shellbark hickories. The nuts of this species are small, white, warped at the ends, and marked by four distinct angles, which correspond to the divisions of the husk.

“The Shellbark nut contains a fuller and sweeter kernel than any American walnut except the Pecan. These nuts are in such request, that they form a small article of commerce, registered on the list of exports of the products of the United States. This exportation, which does not exceed 4 or 500 bushels annually, takes place from New York and from the small towns of Conestoga, to the Southern States, to the West India islands, and even to Liverpool, where the fruit is known by the name of Hickory nuts. In the market of New York they are sold at two dollars a bushel. They are gathered in the forests, and from insolated trees which in some places have been spared in clearing the lands: a precaution which I have particularly noticed to have been used near Goshen, in New Jersey, and on several estates about 30 miles beyond Albany.

“The Indians who inhabit the shores of Lake Erie and Lake Michigan lay up a store of these nuts for the winter, a part of which they pound in wooden mortars, and boiling the paste in water, collect the oily matter which swims upon the surface to season their aliments.

“A cannot forbear mentioning a fine variety of Shellbark nuts, produced upon a farm at Seacoos, near Snake-hill, in New Jersey. They are nearly twice as large as any that I have seen elsewhere, and have a white shell, with rounded prominences instead of angles. A century of cultivation, perhaps, would not advance the species generally to an equal degree of perfection, and probably this variety might still be improved by grafting."

7. **Thick Shellbark Hickory** (**Juglans laniana**). *“This species,” says Michaux, “bears a striking analogy to the preceding, and is frequently confounded with it by the inhabitants of the western country: some of them distinguish it by the name of Thick Shellbark hickory, which should be preserved as its appropriate denomination. East of the Alleghanies this tree is rare, and is found only in a few places; it grows on the Schuylkill river 30 or 40 miles from Philadelphia; in the vicinity of Springfield, 15 or 20 miles from Philadelphia, where its fruit is called Spring- field nut. It is also found in Gloucester county, in Virginia, under the name of Gloucester walnut. These different denominations confirm my observation, that this species is little multiplied on the eastern side of the Alleghany mountains; a fact of which I became assured in travelling through the country. It abounds, on the other hand, in the bottoms which skirt the Ohio and the rivers which empty into it, where it unites with the honey locust, black maple, hackberry, black walnut, wild cherry, white and red elm, box elder, white maple, and buttonwood, to form the thick and gloomy forests which cover these valleys. Like the Shellbark hickory, it grows to the height of 80 feet, and its ample head is supported by a straight trunk, in diameter proportioned to its elevation. The bark exhibits the same singular arrangement with that of the Shellbark hickory; it is divided into strips from 1 to 3 feet long, being warped outwards at the end, and attached only in the middle. They fall, and are succeeded by others similarly disposed. It is only observable that in this species the plates are narrower, more numerous, and of a lighter colour.

“The Thick Shellbark hickory, as has been said, is nearly related to the Shellbark hickory, and its wood, which is of the same colour and texture, unites the peculiar qualities of that species with such as are common to the hickories. Its fruit, though larger, is inferior in taste, and this consideration should induce proprietors in the western country, in clearing their new lands, to spare the true Shellbark hickory in preference, when both species are found upon the same soil.”

8. **Pignut Hickory** (*Juglans porcina* of Michaux, *Carya porcina* of other naturalists), also called Broom hickory. *“This species is generally known in the United States by the name of Pignut and Hognut hickory, sometimes also by that of Broom hickory. The names of these are most commonly in use; the others are known only in some districts of Pennsyl-
HICKORY.

vania, and particularly in the county of Lancas-
ter. Portsmouth in New Hampshire may be
considered as limiting towards the north the
climate of this tree. A little farther south it is
abundant, and in the Atlantic parts of the
Middle States it helps, with the Mockernut
hickory, white oak, swamp white oak, sweet
gum, and dogwood, to form the mass of the
forests. In the Southern States, especially near
the coast, it is less common in the woods, be-
ing found only on the borders of swamps and
in places which are wet without being abso-
lutely marshy or exposed to be long inundated.
This tree is met with in the western country,
but less frequently, I believe, than the Thick
Shellbark and Mockernut hickories. I have
observed that the last mentioned species grows
wherever the Pignut is found, but that the Pig-
nut does not always accompany the Mockernut,
which is satisfied with a less substantial soil.
This remark I have made more particularly in
the lower parts of Virginia, of the two Caro-
linas, and of Georgia. It appears, then, that,
with the exception of the States of Vermont
and New Hampshire, of the District of Maine,
of the Genesee country, and of the cold and
mountainous tracts along the whole range of
the Alleghany mountains, this tree is more or
less abundant in the forests throughout the
United States.

"The Pignut hickory is one of the largest
trees in the United States. It grows to the
height of 70 or 80 feet, with a diameter of 3 or
4 feet.

"The nut is small, smooth, and very hard on
account of the thickness of the shell. Its ker-
nel is sweet, but meager and difficult to extract,
from the firmness of the partitions. These nuts
are never carried to market, but serve for food
to swine, racoons, and the numerous species of
squirrels which people the forests.

"In the Pignut hickory the form and size of
the nuts vary more than in the other species.
Some are oval, and when covered with their
husks, resemble young figs; others are broader
than they are long, and others are perfectly
round. Among these various forms some nuts
are as large as the thumb, and others not bigger
than the little finger."

This tree, so named by Michaux from the re-
semblance of its fruit to the nutmeg, is found in
the Southern and Southwestern States. The
nuts are very small, smooth, and of a brown
colour, marked with lines of white. The husk
is thin, and somewhat rough on the surface.
The shell is so thick as to constitute two-thirds
of the volume of the nut. The kernel is there-
fore very minute, and the fruit even inferior to
that of the Pignut.

Properties and Uses of Hickory Wood.—The
wood of all the species of hickory bears a
striking resemblance, both as to fibre and the
uniform reddish colour of the heart. It pos-
sesses great weight, strength, and unusual plia-
bility and toughness. When exposed to heat
and moisture it is subject to rapid decay, and
is peculiarly liable to injury from worms.

Throughout the Middle States it is selected
for the axle-trees of carriages, for the handles of
axes and other carpenter’s tools, and for large
screws, particularly those of bookbinder’s
presses. The cogs of mill-wheels are made of
hickory heart thoroughly seasoned; but it is
proper only for such wheels as are not ex-
posed to moisture; and for this reason some
other wood is by many mill-wrights preferred.
The rods which form the back of Windsor
chairs, coach-whip-handles, musket-stocks,
rake-teeth, flails for thrashing grain, the bows
of yokes, or the elliptical pieces which pass
under the necks of cattle: all these are objects
customarily made of hickory. At Baltimore it
is used for the hoops of sieves, and is more
esteemed than the white oak, which is equally
elastic, but more apt to peel off in small shreds
into the substance sifted. In the country near
Augusta in Georgia, I have remarked that the
common chairs are of hickory wood. In New
Jersey it is employed for shoeing sledges, that
is, for covering the runners or parts which
slide upon the snow; but to be proper for this
use it must have been cut long enough to have
become perfectly dry.

"Of the numerous trees of North America
east of the Alleghany mountains, none except
the hickory is perfectly adapted to the making
of hoops for casks and boxes. For this pur-
pose vast quantities of it are consumed at
home, and exported to the West India islands.
The hoops are made of young hickories from
6 to 12 feet high, without choice as to the spe-
cies. The largest hoop-poles sold at Philadel-
phia and New York in February, 1808, at $3 a
hundred. Each pole is split into two parts,
and the hoop is crossed and confined by notches
instead of being bound at the end with twigs
like those made of chestnut. From the solidity
of the wood, this method appears sufficiently
secure.

"When it is considered how large a part of
the productions of the United States is packed
for exportation in barrels, an estimate may be
formed of the necessary consumption of
hoops. In consequence of it, young trees
proper for this object have become scarce in
all parts of the country which have been long
settled. The evil is greater, as they do not
sprout a second time from the same root, and
as their growth is slow. The wood does not
cannot lay up a store of them for future use, for
unless employed within a year, and often within
six months after being cut, they are attacked
by two species of insect, one of which eats
within the wood and commits the greatest
ravages."

The defects which unfit the hickory for use
in the building of houses, equally exclude it
from the construction of vessels. At New York
and Philadelphia the Shellbark and Pignut
hickories have been taken for keels, and are
found to last as long as those of other wood,
owing to their being always in the water. Of
the two species, the Pignut would be preferra-
able, as being less liable to split, but it is rarely
found of as large dimensions as the other.

"In sloops and schooners the rings by which
the sails are hoisted and confined to the mast
are always of hickory. I have also been as-
ured that for attaching the cordage it makes
excellent pegs, which are stronger than those
of oak; but they should be set loosely in the
HICKORY CATEPILLAR.

holes, as otherwise, for want of speedily season, they soon decay. For handspikes the hickory is particularly esteemed on account of its strength; it is accordingly employed in most American vessels, and is exported for the same purpose to England, where it sells from 50 to 100 per cent. higher than ash, which is brought also from the north of the United States. The hickories are cut without distinction for this use, but the Pignut, I believe, is the best.

"All the hickories are very heavy, and in a given volume contain a great quantity of combustible matter. They produce an ardent heat, and leave a heavy, compact, and long-lived coal. In this respect no wood of the same latitude in Europe or America can be compared to them; such, at least, is the opinion of all Europeans who have resided in the United States. "It has been seen by what precedes, that though hickory wood has essential defects, they are compensated by good properties which render it valuable in the arts."

In concluding this article, Michaux recommends particularly for propagation in European forests the Shellbark hickory and the Pignut hickory, whose wood unites in the highest degree the valuable properties of the group. He thinks, also, that the Paeanenut merits attention from promoters of useful culture, not so much for its wood as for its fruit, which is excellent, and more delicate than that of the European walnut. It might probably be doubled in size, if the practice was successfully adopted of grafting this species upon the black walnut, or upon the common European walnut.

HICKORY CATERPILLAR. Whilst the wood of the hickory is preyed upon by borers, the foliage suffers in the latter part of summer from troops of caterpillars covered with short spreading tufts of white hairs, with a row of eight black tufts on the back, and two long, slender, black pencils on the fourth and tenth rings. When fully grown, they are nearly one and a half inch long. They leave the trees in September, make cocoons, which are thin, oval, and hairy. The moths, which come out of the cocoons in the month of June, are of a very light ochre-yellow colour, the wings being sprinkled with brown dots. In England, the moths that come from caterpillars having long pencils and tufts on their backs, are called tussock-moths; and Dr. Harris says we may name the one under consideration the hickory tussock-moth (Lophocampa caryae). They expand their wings from 1½ to 2½ inches or more. The caterpillars found on the black walnut, butternut, the ash, and even the oak, closely resemble the hickory caterpillar in shape, but not in colour. They belong to a different species.

HICKORY TREE BORER. The hickory tree is much exposed to the ravages of the larva of wood-eating insects or borers, which not only attacks the trees of the forests, but those of orchards, especially after they have passed their prime. The transformation of the insects in the trunks and limbs of the trees. "The larva," says Dr. Harris, "that are known to me have a close resemblance to each other; a general idea of them can be formed from a description of that which attacks the Pignut hickory. It is of a yellowish-white colour, very long, narrow, and depressed in form, but abruptly widened near the anterior extremity. The head is brownish, small, and sunk in the fore-part of the first segment; the upper jaws are provided with three teeth, and are of a black colour; and the antennæ are very short. These grubs are found under the bark and in the solid wood of trees, and sometimes in great numbers. They frequently rest with the body bent sidewise, so that the head and tail approach each other. This posture those found under bark usually assume. They appear to pass several years in the larva state. The pupa bears a near resemblance to the perfect insect, but is entirely white, until near the time of its last transformation. Its situation is immediately under the bark, the head being directed outwards, so that when the pupa-coat is cast off, the beetle has merely a thin covering of bark to perforate, before making its escape from the tree. The form of this perforation is oval, as is also a transverse section of the burrow, that shape being best adapted to the form, motions, and ingress of the insect.

"Some of these beetles are known to eat leaves and flowers, and of this nature is probably the food of all of them. The injury they may thus commit is not very apparent, and cannot bear any comparison with the extensive ravages of their larva. The solid trunks and limbs of sound and vigorous trees are often bored through in various directions by these insects, which, during a long-continued life, derive their only nourishment from the woody fragments they devour. Pines and firs seem particularly subject to their attacks, but other forest trees do not escape, and even fruit trees are frequently injured by these borers."

A borer belonging to another family of beetles is also found in the hickory, namely, the larva of the beetle called by naturalists Steno-corax cinctus, or banded stenocorax, the generic name signifying narrow or straitened. Long galleries, running in the direction of the fibres, are made by this grub in the hard wood of the hickory. The beetle is of a hazel colour, with a tint of gray, arising from the short hairs with which it is covered. There is an oblique ochre-yellow band across each wing-cover. (Harris.)

HIDE-BOUND. In farriery, applied to a certain disease of cows and horses, in which the skin adheres to the sinews. Want of proper care, spare diet, and bad food, such as rank long grass in swampy situations, and musty hay or oats, are the most probable causes of this affection. Hide-bound is rarely a primary disease; it is a symptom of unhealthiness, and often of disease, of the digestive organs. It is sometimes an accompaniment of chronic cough, grease, farcy, and founder. A few mashes, and a mild dose of physic, often have a very beneficial effect. If the horse cannot be spared for physic, the following alternative, which is in common use, may be given every night for some time in a mash, or in the form of a ball: levigated antimony, 2 drachms; nitre, 3 drachms; sulphur, 4 drachms. For the cow, eight ounces of sulphur, with half an ounce of ginger, and
a few mashies should be given. (Lth. of Use. Known; The Horse, p. 571; Cattle, p. 571.)

HIDE OF LAND (Sax. hyd; Germ. haute; Dutch, hooide) is a skin, especially the skin of a cow, and is applied to the skins of most beasts; but in commerce it is limited to the strong and thick skin of the horse, ox, and other large animals. Hides are raw or green; that is, in the state in which they are taken off the carcass, or dressed with salt, alum, and saltpetre, to prevent them from putrefying; or they are cured or tanned. The hides of South America are in the highest repute, and vast quantities of them are annually imported into Great Britain. Large quantities are also received from various parts of the continent, and from Morocco, the Cape of Good Hope, &c. About 200,000 cwt. of untanned hides are annually imported, and about 120,000 cwt. of other hides, exclusive of Russia hides, which form a large proportion of the imports. The rate of duty charged on hides is—untanned, dry, per cwt., 4s. 8d.; wet, 2s. 4d. ditto; pieces of hide, or hides tawed, curried, or dressed, 9d. per lb.; cut or trimmed, 1s. 2d. per lb. Those imported from British colonies are only liable to half this rate of duty.

HIGHWAYS retain their name from the Roman method of elevating the road upon causeways, or by raised earth. In the English common law, highways are roads common to all the Queen's subjects, which the parish are liable to repair. All ways, either for foot passengers, or carriages and horses, are properly highways. If a road is dedicated to the public for 25 years, it becomes a highway, which the parish are bound to repair, although they have not acquiesced in the dedication of the road. And if a road has been freely used by the public for 4 or 5 years, a jury is warranted in presuming that the owners of the soil consented to its being thus used. Bridges in highways become public by whomsoever built, but not raised causeways furnished with culverts over meadows, if more than 300 feet from the bridge; and a bridge only used by the public in periods of floods, is merely a public bridge during that period. By the common law, the obligation to repair the road lies upon the parish; the bridges are to be repaired by the county, and not only the bridge, but since the 22 Henry VIII. c. 5, s. 9, the road or approaches for 300 feet "from any of the ends of it." Surveyors of the highways are now annually elected by the parishioners on or within 14 days of the 25th of March (5 and 6 W. IV., c. 50, s. 6); and the surveyor may be, by sect. 6 of this act, re-elected, who must serve, under a penalty of 20l.: he is entitled, however, to a salary; by s. 26, he is liable to a penalty of 5l. for neglect of duty. The surveyor, by s. 25, is authorized to use adjoining grounds as a temporary highway, whilst the old road is repairing; and, by s. 27, he is empowered to make a rate on the inhabitants, which must, however, be allowed by the justices. By s. 47, any person taking road scrapings or other materials from the sides of roads, is liable to a penalty of 10l. The surveyor is empowered to dig for road materials within his own, or any other parish, and to gather stones free from charge, on any land within his parish, but he must pay for any damage done to the land during their removal; and after obtaining license from the justices, he may enter upon and dig for road materials, making, however, satisfaction to the owners; and he must fill up the holes he makes, or have them filled up and sloped down. No tree shall be allowed to be planted within 15 feet of the centre of the highway; and with the authority of a justice of the peace (after duly summoning the owner to show cause), the surveyor may order hedges and trees, which shade or otherwise injure highways, to be cut and plashed. Cartways must be 20 feet, horseways 8, and footways 3 feet wide.

A surveyor of highways is not personally liable to the labourers; they must look to the commissioners, or their treasurer. A way warden may charge law expenses incurred in the discharge of his duty.

Repairing Roads.—The advantages of keeping roads in repair, if only regarded by the farmer as lessening the draught of his horses, may be estimated from the following table of the average force required to draw a light four-wheeled cart, weighing, with its load, 1000 pounds:

<table>
<thead>
<tr>
<th>Description of Road</th>
<th>Force of traction required to move the cartage</th>
</tr>
</thead>
<tbody>
<tr>
<td>Turnpike road—hard dry</td>
<td>301 lbs.</td>
</tr>
<tr>
<td>Turnpike road—dirty</td>
<td>39</td>
</tr>
<tr>
<td>Hard, compact loam</td>
<td>53</td>
</tr>
<tr>
<td>Ordinary by-road</td>
<td>106</td>
</tr>
<tr>
<td>Turnpike road, newly gravelled</td>
<td>143</td>
</tr>
<tr>
<td>Loose sandy road</td>
<td>204</td>
</tr>
</tbody>
</table>

The annual expense of repairing the roads throughout England, according to a report of a committee of the House of Commons in 1814, amounted to 1,500,000l., which Mr. Penfold in his Treatise on Road-making, divides into

Materials, tradesmen, and officers | £500,000 |
Manual labour | 420,000 |
Carriage | 750,000 |

The chief points to be attended to in road making are—1, the foundation; 2, the drainage; 3, the choice of the materials; 4, the preparation of them; and 5, the size of them. In repairing—1, the scraping; 2, the removal of shading trees, &c; 3, the watering. A careful
HOLCUS.

Hippopathology.

The slightest protection, even that of a bush, thin sprinkling of straw or litter, is sufficient to prevent the deposition of frost, because it is only necessary to prevent radiation.

Hoewing by Hand. The hand hoe is an instrument too well known to need any description. The operation of hoewing is beneficial, not only as being destructive of weeds, but as loosening the surface of the soil, and rendering it more permeable to the gases and aqueous vapour of the atmosphere. Hoewing, therefore, not only protects the farmer's crops from being weakened by weeds, but it renders the soil itself more fertile, as more capable of supplying the plants with their food. Jethro Tull was the first who warmly and ably inculcated the advantages of hoeing cultivated soils. He correctly enough told the farmers of his time, that as fine hoed ground is not so long soaked by rain, so the dews never suffer it to become perfectly dry. This appears by the plants which flourish in this, whilst those in the hard ground are starved. In the driest weather good hoewing procures moisture to the roots of plants, though the ignorant and incurious fancy it lets in the drought.

Hogs. See Swine.

Hogweed (Heracleum sphondylium). The weed known by this name in Pennsylvania and other Middle States, is also called Rag-weed and Bitter-weed, the Ambrosia Elatior or Taller Ambrosia of botanical writers. This apparently very worthless weed is common in pastures and cultivated fields, always following the wheat crop immediately after harvest, as though a parasite of this species of grain. If the land be good, the plant seems to give place, the following season, to the crop of clover or timothy. "I have," says Dr. Darlington "been puzzled to determine this species satisfactorily. It is evidently, I think, the Ambrosia Elatior of Bigelow, and some others, and as clearly the A. artemisinifolia of Barton, &c.; whilst, at the same time, it agrees pretty well with Elliott's A. paniculata. Are they all distinct species? Five or six additional species are enumerated in the United States." (Flor. Cestr.)

This plant comes into flower about the middle of May; its nutritive powers appear to be considerable when compared to those of lucern and some other plants. Sinclair found that 64 drs. of the herbage afforded of nutritive matter 90 grs., lucern an equal proportion, the same weight for burnet and of Bunias orientalis 100 grs. each, of the broad-leaved cultivated clover 80 grains. See Cow-Parsnip. (Hort. Gram. Wob. p. 411.)

Holcus. The soft-grass. A genus of grasses of which Smith, in his Eng. Flor. (vol. i. p. 107), describes three species, but which colder than that only four feet from the surface. He found, on the 19th of August, 1813 (Trans. High. Soc. ix. 250):—

<table>
<thead>
<tr>
<th>Time</th>
<th>On the ground</th>
<th>Four feet from the ground</th>
</tr>
</thead>
<tbody>
<tr>
<td>6 h. 45 m</td>
<td>53°</td>
<td>60°</td>
</tr>
<tr>
<td>7 h.</td>
<td>51°</td>
<td>58°</td>
</tr>
<tr>
<td>7 h. 20 m</td>
<td>49½</td>
<td>59</td>
</tr>
<tr>
<td>7 h. 40 m</td>
<td>49</td>

</tbody>
</table>

To which points will well repay the risk for the care bestowed upon them. Here is a paper, by Mr. Whyte, upon a machine for scraping and cleansing highways (Trans. High. Soc., vol. iv. p. 349), and on roads, and the excessive weights carried on them in narrow-wheeled wagons, by Mr. Whelly (Com. to Board of Agr., vol. vi. p. 182), and there is a work on road-making by Sir C. M'Adam, which every road-surveyor should possess. Sir Henry Farnell has also published a valuable treatise on road-making. Of the materials best adapted to road-making, Mr. Penfold remarks, "The trappean and basaltic rocks are those best suited for the construction of roads. No material has ever been used superior to the tough basals, which are brought as ballast in ships from China and Bombay, and which have been partially used in the macadamised streets of London. Limestones, in many respects, afford an excellent material. The more unyielding the material, the smaller is the size to which it ought to be broken. Limestones have in general a peculiar quality of making smooth roads, even if not broken to a small size. Pit gravel, especially that belonging to the new red sandstone formation, is in general not to be depended upon, as containing stones of different sorts, and consequently of different degrees of strength. It is one of the greatest mistakes in road-making to lay on thick coats of materials. If there be substance enough already in the road, and which, indeed, should always be carefully kept up, it will never be right to put on more than a stone's thickness at a time."
HOLCUS.

Sinclair, in his *Hortus Grassiueus*, has extend-
ed to 5 species and varieties, including the northern holy-grass (*Hierochloe borealis*), which Smith very properly refers to another class.

**Holcus arenaceous** *(Pl. 5, cc).* Tall oat-like
soft-grass. In this species the calyx is smooth, the barren floret lowest, with a sharply bent prominent awn; fertile one bent, slightly ele-
vated, scarcely awned; leaves rather harsh; roots knobbled, or with tuberous joints and
downy fibres. In dry or fluctuating soils the roots become largely bulbous, and then constitu-
tute a troublesome weed. In the works of
Linnaeus, Curtis, and Host, this grass is found
under the name of *Avena elatior*; it has since
been thought to agree better with *holcus* in
structure; but it appears to belong to neither
of these justly, serving rather to form the con-
necting link between the *avena*, *halei*, and *aira*.
This grass grows common in pastures, hedges,
thickets, and by road sides. The stem rises to
3 feet high, is smooth, simple, and jointed; the
joints sometimes downy; the leaves are deep-
green, rough-edged, and rather harsh to the
touch, with long striated sheaths, and abrupt
stipules. The flowering panicle is erect, late-
ral. The seeds are nearly cylindrical, and
coated with the hardened corolla. This grass
sends forth flowering culms during the whole
of the season. The entire plant is subject to
rust after the period of flowering; hence the
crop should be cut as soon as the grass is in
flower. This grass is eaten by all sorts of cat-
tle, and is always present in the composition of
the best natural pastures; but it does not
constitute a large proportion of the herbage.
It perishes rapidly after being cropped; and
though later in flowering (end of June) than
many other species, produces an early and
plentiful supply of herbage in the spring.
These properties would-entitle it to rank high
as a grass adapted for the alternate husbandry,
but with respect to its nutritive properties, it
contains too large a proportion of bitter extrac-
tive and saline matters to warrant its cultiva-
tion without a considerable admixture of dif-
ferent grasses; and the same objection extends
to its culture for permanent pasture.

**Holcus arenaceous**, var. nuticus. Awnless, tall,
oat-like soft-grass. In this variety, which is
smaller in every respect than the preceding,
the leaves are very short, the roots slightly
tuberous, the panicle much contracted, the
flowers without awns; glumes pencilled at the
apex with purple. It flowers a week later than
the awned variety; in all other respects it is
the same. It seldom perfects any good seed, and
appears to be much inferior in point of produce.
Hares give a decided preference to the
awnless variety.

**Holcus lanatus.** Woolly or meadow soft-
grass. The root in this species is fibrous; the
stem simple, 1½ to 2 feet high, smooth above,
hairy below, with hairy sheaths, and short
blunt stipules. The panicle is thrice compo-
und, erect, and spreading. The calyx of the
flower is woolly, lower floret perfect, awnless;
upper with an arched awn; leaves downy on
both sides. This is a very troublesome grass,
which is difficult to get rid of; it grows abun-
dant in meadows and pastures on all soils, from
the richest to the poorest. Cattle prefer almost
any other grass to this; hence it is seen in
pastures, with full-grown perfect leaves, while
the grasses that surround it are cropped to the
roots. Sir Humphry Davy has shown that its
nutritive matter consists entirely of mucil-
gage and sugar; while the same property in
the grasses most relished by cattle has either
a sub-acid or saline taste. This grass might
probably be rendered more palatable to cattle
by being sprinkled over with salt.

Hard stocking, and never suffering it to run
to seed, will at least prevent this grass from
spreading; but ploughing up the pasture, and
taking not less than a five years' course of
crops and then returning the land to other
grases, will be found the best means of getting
rid of it. It flowers and ripens the seed in July.

**Holcus mollis.** Creeping soft-grass. *Pl. 5, c.*

Couch-grass. The specific character of this
species is, root creeping; calyx partly naked, lower floret perfect, awnless, upper with a
sharply bent prominent awn; leaves slightly
downy. The distinctions between this grass
and the woolly or meadow soft-grass, *H. lana-
tus*, are the creeping root, and the whole plant
being more slender and less downy. The
leaves are also narrower and more soft than
those of the *H. lanatus*, and grow more distinct
from each other: on the contrary, those of the
*H. lanatus* are in dense tufts. The panicle is
more loose and smoother, with conspicuous
awns, which, in drying, bend at a right angle,
and extend beyond the calyx. The panicle of the
*H. lanatus* is generally of a reddish purple
colour tinged with green, or, when growing
under the shade of trees, of a whitish-green
colour. The panicle of the *H. mollis* is always
of the latter colour. This grass would rank as
one of the superior grasses if it did not usually
tenant a light bare sandly soil; but it produces
little herbage in the spring, and the aftermath
is next to nothing. Pigs are very fond of the roots,
which contain a very considerable quantity of
nutritive matter, having the flavour of new-
made meal. The herbage is apparently more
disliked by cattle than that of the *H. lanatus*:
it is extremely soft, dry, and tasteless. The roots,
when once in possession of the soil, can hard-
ly again be expelled without great labour and
expense. It is the true couch grass of light
sandy soils, for its roots frequently attain in a
few months to 4 or 5 feet in length. The best
mode of banishing this impoverishing and
troublesome weed from light arable lands that
are infested with it, is to collect the roots with
the fork after the plough; and when thus in
some measure lessened to apply yearly dress-
gings of clay, perhaps 50 loads per acre, till the
texture of the soil is changed to a sandy loam;
this grass will then be easily overcome, and
the fertility of the soil permanently increased.

See COUCH.

**Holcus odoratus** *(repens).* Sweet-scented soft-
grass or northern holy-grass. See Holy-
Grass.

I have placed together in a tabular form the
comparative yield of produce of these grasses.
*(Sclater's Hort. Gram. Wob.)*

627
HOLLEY. (Ilex aquifolium). A handsome evergreen tree, of slow growth, with a smooth, gray bark, which, abounding in mucilage, makes bird-lime by maceration in water. The wood is hard, close-grained, and covered with the above smooth gray bark. The leaves are alternate, stalked, rigid, shining, waxy, with spinous divericated lobes; the upper ones on one trees entire, with only a terminal prickly. The flowers are copious, white, tinged externally with purple, the earlier ones least perfect. The berries are scarlet, casually yellow. The holly grows in hedges and bushy places upon dry hills. Numerous variegated varieties are kept in gardens, and one whose leaves are prickly on the disk. Darwin suggested the idea, that the points on the lower leaves of the holly was a provision of nature to prevent them from being eaten by cattle; hence, when the tree grows beyond the reach of the cattle, the leaves lose the pines, that species of armorature being no longer necessary. The tree bears clipping well; but it is not so fashionable for cut hedges as formerly. The branches, laden with berries, are stuck about rustic kitchens and churches at Christmas, and remain till Candlemas Day. In Norfolk and some other English counties the missel-hoe accompanies them, and sometimes branches of the spindletree or prickwood. The common holly of the United States is the Ilex opaca of naturalists, a handsome evergreen which, though in some of the Middle States a mere shrub, in others assumes the dignity of a tree. In Kent county, Delaware, the holly frequently attains a height of 30 to 40 feet. Seven or eight additional species are found in the United States, chiefly in the south.

HOLM (Sax. and Danish). An island or fenny place surrounded by water.

HOLM OAK, or HOLLY OAK. See OAK.

HOLT (Sax. a wood; Germ. holz). The termination of many names of places in England, derived from their ancient situation in a wood.

HOLY-GRASS, NORTHERN (Hierochloe bonariensis). The sweet-scented soft-grass, Holcus odoratus (repens) of some botanists. The powerful creeping roots of this grass, its tender nature, and the great deficiency of foliage in the spring are demerits which discourage the idea of recommending it further to the notice of the agriculturist. It comes into flower about the end of April, and perfects hardly any seed; but few grasses propagate more, quickly by the roots. This grass is said to be used at high festivals, for strewing the churches in Prussia, as Arcturus calamus has time out of mind been employed in the cathedral and streets of Norwich on the mayor's day.

HOMESTEAD, or FARM STEADING. A collection of farm buildings and offices arranged in a convenient form.

HONEY (German, honig). A well-known vegetable substance collected by bees. "Its flavour," says Dr. A. T. Thomson, "varies according to the nature of the flowers from which it is collected. Thus, the honeys of Minorca, Narbonne, and England are known by their flavours. It is separated from the comb by dripping, and by expression; the first method affords the purest sort, the second separates a less pure honey, and a still inferior kind is obtained by heating the comb before it is pressed. When obtained from young hives which have not swarmed, it is denominated virgin honey. It is sometimes adulterated with flour and starch, which may be detected by mixing it with tepid water: the honey dissolves, while the flour or starch remains nearly unaltered." Honey is easily soluble in water, and, like sugar, readily undergoes the vinous fermentation; in this way, in fact, mead is made, an intoxicating beverage, once much more extensively prepared than now.

Honey constitutes a very important product of some countries, among which we may name Poland, where the management of bees is an extensive branch of forest culture. Poland honey is commercially divided into three classes; the finest, called lipiec, is gathered by the bees from the lime tree alone, and is considered on the Continent most valuable, not only for the superiority of its flavour, but also for the estimation in which it is held as an arcanum in pulmonary complaints, containing very little wax, and being, consequently, less heating in its nature; it is as white as milk, and is only to be met with in the lime forests in the neighbourhood of the town of Kowno, in Lithuania. It is the June and July work alone that constitutes this delightful product, and which is carefully taken from the hives, in which is left for the store of the bees the honey collected by them before and after the flowering of the linden, a tree quite different from all the rest of the genus Tilia, and called Kaniemipus, or Stone Lime.

The lessny, the next class of honey, which is inferior in a great degree to the lipiec, being only for the common mead, is that of the pine forests.

The third class of honey is the stepowy pusznyjny, or the honey from meadows or places where men employed in the cathedrals of perennials, and hardly any wood. The province of Ukraine produces the very best, and also the very best wax. In that province the peasants pay particular attention to this branch of economy, as it is the only resource they have to enable them to defray the taxes levied by Russia; and they consider the produce of bees equal to ready money.
HONEY.

In the United States, the capacity to produce honey seems only limited by the ravages of that great pest, the bee-moth. Over this, however, it is to be hoped ingenuity will finally triumph, if it has not done so already. See Bees and Bee-moth.

Russian System of managing Bees and constructing Hives.

In Russia and other northern parts of Europe, honey and wax constitute great sources of private wealth and general trade. A large amount of this honey is obtained from trees in the wild forests, which, when not hollowed by nature, are scooped out by man for the accommodation of swarms, nails being driven into the body, to prevent the bears from climbing up and getting at the honey. This primitive plan may be called the Forest system, to distinguish it from another, consisting of large assemblages of hives, entitling it to the appellation of the Camp system. These bee-camps are often removed from place to place, according to the abundance or scarcity of flowers. A new system of managing bees has been lately introduced into Russia, which has acquired immense celebrity, not only in that country, but in other parts of continental Europe, to the northern portion of which it may perhaps be more specially adapted. It is, however, at present receiving great encouragement in France, where the most active efforts are making to promote its extension. Although we believe that the most essential objects obtained by the Russian mode are gained through some of the almost innumerable contrivances worked out by American ingenuity, still we think it proper to make the citizens of the United States acquainted with what is deemed of so much individual and national importance abroad.

The Russian system owes its origin and establishment to M. Prokopovitch, an individual who has devoted more than half his life to the subject. His reputation as an apianist is at present so high as to have enabled him to establish an extensive school for teaching the art of managing bees. His school and dwelling-houses are situated in the midst of a vast garden, in which are found no less than twenty-eight hundred hives. The number of his pupils is never under eighty, which come from all parts of Russia, and remain two years. His terms are very moderate.

In studying the nature and characteristics of the queen, he made the discovery that she always keeps upon the honeycomb, and never creeps upon any part of the hive. This observation has turned to advantage, so as to make the bees assort and dispose their honey in whatever manner he desires it to be deposited.

By discovering a plant pre-eminent in honey, he has rendered another service to his country, not less useful than that just referred to. This is the Echium Vulgare, called in Russia Ciniak. It has long been known to abound in the materials of honey, but had always been left in a wild state until this intelligent Russian took it into regular cultivation for the use of his bees. In doing this, says a French writer, he has rendered a service to Europe similar to that conferred by Parmentier, who placed the potato among the number of plants indispensable to the purposes of domestic economy. Many of the Russian provinces possess only a very few plants rich in honey; or, rather, owing to the rigours of the climate, the plants furnish honey during a very short period. The Echium is therefore the more valuable from the fact that it is so little sensible to the effects of both heat and cold, neither of which cause it to part with its mellifluous qualities. Even after the setting in of white frosts, which ordinarily commence about the end of September or first of October, it still continues to flower.

It is proper to observe that the plant which has thus acquired such great celebrity bears the same name with a common and very beautiful English wild plant, belonging to the Bo-rage family, and that, in his Flora Cestrica, Dr. Darlington describes the common Echium as a foreign weed, extremely troublesome in some portions of the United States, though as yet rare in Chester county, Pennsylvania. A species called Viola Echium is cultivated in some flower-gardens in the United States, but no American species has yet been pointed out by botanists. The French call the common Echium Vipers fr, and Herbe aux Vipères; the Germans, Wicd Ochsenzunge, and Dr Natterkopf. The popular names in the United States are Blue Weed, Blue Devils, and Viper's Engloss. It is highly probable that the plant so much prized in Russia is a variety of Borage differing considerably from the weed denounced by Dr. Darlington. His caution, however, ought by no means to be forgotten by persons who introduce the Echium for the benefit of their bees, as it is a biennial, furnished with a very thick and hard tap-root, which must be very difficult to get out of ground when it has once gained possession. It should therefore be sown and kept in places where it may be restrained within bounds. It may be popularly described as a plant with long and rather narrow leaves, coming to a point, which leaves, with the stalks, are covered with a profusion of hairs. It puts out numerous spikes bearing one or two bell-shaped flowers, of a purple-blue colour, having five petals, which are pubescent or hairy. It produces small, rough, and brownish oval-shaped nuts, which are angular on the inner side. (See Fig. 6, on the Plate representing the Russian Bee-hive, etc.)

Description of the Russian Bee-hive.

Fig. 1 represents the hive in perspective, supported upon a floor of brick or stone, carried beyond the sides of the hive, so as to secure a solid foundation. The usual size of this hive is three feet six inches in height, fourteen, twenty, and even as much as twenty-two inches in width, and from sixteen to sixteen and a half inches in depth. The box or case is made of five boards, either nailed, or, what is better, dovetailed together. The pieces represented at a, a, a, are three doors of equal size, which are fixed into mortices or grooves and fastened by the pegs b, b. c, c, are two movable pieces, an inch wide, upon which the movable doors 3 a 2

629
HONEY.

rest. \( d \), small slats fastened into the sides of the hive by mortices. These serve to prevent the doors from touching the honeycomb. Each range of frames has one of these slats.

\( e, f, f \) are small frames in which the bees work and deposit their honeycombs. These frames are notched or scooped out circularly upon the lower side, as well as upon both edges of the front end, as represented in fig. 2. The opening left by the hollow in the lowermost side serves for the bees to enter from beneath, whilst the hollows on the two sides of the front end of the frame admits the movements of the bees to be observed. These frames are thin; their thickness, however, is not arbitrary, but must be made to correspond to the size and form which the bees give to their combs.

When placed side by side the frames must not touch, but a small space is to be left between to allow a little play, and prevent them from wedging together and becoming light in warm weather, when the wood swells.

\( f, f, f \) are three places of entrance for the bees, furnished with slides. These are so arranged that the middle one comes exactly in the middle of its compartment; the upper one is an inch higher than the intermediate; whilst the lower opening is an inch lower than the lowermost slat.

\( h \) (fig. 3) is a grating to be used in autumn, when it may be desired to separate the empty parts from those filled with comb. This grating, or adapter, remains in contact with the bees.

\( g \) (fig. 4) represents a small board, which is to be placed on top of the grating.

Fig. 5 is a transverse section, in which may be seen the places of entrance to the depth of the frames, \( a \), and \( c \), one of the combs.

The various kinds of hives, constructed in sections or compartments, may be divided into two classes, namely,—those in which the divisions are made either horizontally or vertically.

The first are founded upon the well-known necessity for allowing space for the new combs; the second from the advantage derived from separating the swarms artificially. To carry out these plans, very complicated contrivances have generally been employed, whilst the Russian hive effects the very necessary object to be gained from section or division hives.

The leading principle of the Russian hive, which, it will be seen, is quite plain in construction, and economical as to first cost,—consists in its capacity to be reversed or turned upside down, a very simple operation, which, however, leads to the most important results in the management of bees.

Reversing the hive not only allows of the perfect renewal of the wax, but furnishes an opportunity of inspecting every thing passing within, by means of the movable doors, and at the same time, of conducting all the operations at pleasure, thus uniting all the advantages of the two systems of horizontal and vertical section hives, such as the separation of swarms, &c.

By means of the operation of reversing, the bee-manager who introduces a swarm into the Russian hive, will, during three years, be able to withdraw each year one of the three divisions alternately, or one-third of the whole mass of honey deposited; at the end of the period mentioned, he will have thus produced a perfect renewal of the wax; that is to say, at this time he will be obliged to reverse or turn up the hive, the former bottom of which now becomes the top.

The mode in which M. Prokopovích manages to make his bees assort their honey themselves, is effected by means of a very simple contrivance. Many others have devised modes very similar to those adopted by the Russian apiarist, but it is asserted that their objects had not the same end, since they only sought to obtain the virgin honey. No one has hitherto believed it practicable to procure honey of a uniform quality and which at the same time is virgin honey. The idea therefore originally belongs to M. Prokopovích, who, whilst pursuing his apiarian studies, had it suggested to him by a plan adopted by Huber for the mere purpose of being able to watch the habits of bees.

The process of working the Russian hive is as follows: In autumn, after having taken the upper portion of the crop, when the amount of honey admits this to be done, the part of the hive thus left empty is separated from the rest of the comb, by introducing the grating \( h \), and placing upon it the board \( g \). In this state the hive is conveyed to some suitable place to pass the winter. The following summer, at the arrival of the season when the plant from which honey is to be collected is in flower, the board is removed, and the frames \( e \) placed upon the grating. These frames, which are made of very thin stuff, have a length equal to the depth of the frames, or about half that of their length, and their width or thickness ought not to exceed an inch and a half.

Two sides of the frame, have, as already described, two notches or hollows which reduce their width. One of these is the long side which comes in contact with the grating, affording passage to the bees, whilst the other is the end near the door which admits the movements of the bees to be inspected. Before these frames are arranged in their places, a little dry wax is to be stuck along the middle of the upper side of the frame, (the side which is not scooped out). This is for the purpose of directing the bees where they must place their combs.

By the arrangement described, the bees finding above them a vacant space, commence their work in it, and finding in the flowers in bloom sufficient material, fill the cases with honey, and this they do with the more rapidity from the circumstance of this being separated by a space not yet occupied by the combs, and her inability to reach these to lay her eggs in them. The cases in which the honey is deposited are sealed up immediately, the comb is observed to have reached the lower part of the box, and before the queen has had an opportunity of depositing in it any eggs. The honey thus obtained is of remarkable purity, and may be taken to market in the same frames in which it was originally made. These may even be packed up together in cases, and transported in wagons to great distances, without doing the least injury to the honey.
HONEY DEW. See APHIDIAN.

HONEY LOCUST, or Sweet Locust (Glycirsia triacanthos). The sweet locust belongs peculiarly to the country west of the Alleghany Mountains, and it is scarcely found in any part of the Atlantic States, except in Limestone Valley and its branches, which lie between the first and second ranges of the Alleghanies, beginning near Harrisburg in Pennsylvania, in the latitude of 40° 12', and extending from north-east to south-west into the state of Virginia. The soil in this valley is generally very inconsiderable. In the fertile bottoms which are watered by the rivers emptying into the Mississippi, in the Illinois country, and, still more, in the southern part of Kentucky and Tennessee, the sweet locust is abundant. It commonly grows with the black walnut, shell-bark hickory, red elm, blue ash, locust, box elder, and coffee tree, and forms a part of the forests that cover the most fertile soils. In different parts of the United States, this species is called indifferently sweet locust and honey locust; the French of Illinois call it févier.

In situations the most favourable to its growth, such as are observed on the banks of the Ohio, between Gallipolis and Limestone, the sweet locust attains a very ample size. Michaux measured several stocks which were three or four feet in diameter, and which appeared to equal in height the loftiest trees of these immemorial forests. Some of them had the trunk undivided for forty feet.

The sweet locust is easily known by its bark, which, at intervals of a few inches, detaches itself laterally in plates three or four inches wide and two or three lines thick, and by the form of its trunk, which appears to be twisted, and which presents three or four crevices of inconsiderable depth, opening irregularly from the bottom towards the top. The large thorns which cover the branches, and frequently the trunk of young trees, afford another very distinct characteristic. These thorns are sometimes several inches long, lignified of a reddish colour, and armed, at some distance from the base, with two secondary thorns, about half the size of the first.

The leaves of the sweet locust are pinnated, and composed of small, oval, serrate, sessile leaflets. This foliage is elegant, and of an agreeable tint; but it is thin, and scarcely obstructs the passage of the sunbeams. It is shed annually at the approach of winter.

The flowers are small, not very conspicuous, and short-lived. The fruit is in the form of flat, crooked, pendent pods, from twelve to eighteen inches long, and of a reddish-brown colour. The pods contain brown, smooth, hard seeds, enveloped in a pulpy substance, which, for a month after their maturity, is very sweet, and which then becomes extremely sour. Beer is sometimes made by fermenting this pulp while fresh; but the practice is not general, as the apple tree and peach tree, particularly the last, have become common in the western country, and afford a much superior beverage.

The perfect wood or heart of the sweet locust nearly resembles that of the locust, but its grain is coarser and its pores more open: in these respects it is more strikingly characterized than even the wood of the red oak. When perfectly seasoned, it is extremely hard. It is little esteemed in Kentucky, where it is more employed, and consequently can be better appreciated, than elsewhere. It is used neither by the carpenter nor the wheelwright: it is sometimes taken by the farmers for rails to fence their fields, but only when they are unable to procure better wood. It is found by experience to be far inferior to the wild cherry and black walnut for cabinet-making. The only destination for which it appears to be peculiarly adapted, is the forming of hedges, which would be rendered impenetrable by its long thorns.

The sweet locust has been cultivated for many years in Europe. It flourishes, blooms, and yields seed in the climates of London and Paris; but its vegetation is less active than in the south of France. (Michaux.)

HONEY SUCKLE (Lonicera), named after Adam Lonicera, a German botanist, who died in 1586. This is a genus of very ornamental shrubs, closely allied to the genus Caprifolium. The species grow in any common soil, and are readily increased by cuttings taken off in autumn and planted in a sheltered situation. (Poxton's Bot. Dict.)

In the English Flora, by Dr. Smith, three indigenous species are described.

There are five hardy sorts of honeysuckle mentioned by Miller: namely, the Virginian trumpet honeysuckle (L. sempervirens), the German honeysuckle, the Italian honeysuckle, the English honeysuckle or woodbine (L. periclymenum), and the evergreen honeysuckle. He names also three other sorts, which are too tender to raise without artificial heat.

There are two varieties of the trumpet honeysuckle; one is a native of Virginia, and the other is from Carolina. The Virginia trumpet honeysuckle is harder, its leaves are of a darker green, and its flowers are a deeper red than those of Carolina. These plants are weak and trailing; they should therefore be placed against walls and trellis-work.

The German or Dutch honeysuckle is a hardy shrub, which can be formed into a good round head: the flowers are reddish outside and yellowish within, blooming in June, July, and August. Miller mentions two varieties of this honeysuckle, the "long blowing" and the "late red."

The Italian honeysuckle has two varieties, the "early white," which is fragrant, but of short duration, blooming in May; and the "yellow," which bears yellowish flowers, and is succeeded by red berries.

The American or evergreen honeysuckle is the most valuable, for its flowers from June till the frost nips its blooms. It has strong branches bearing evergreen leaves and fragrant flowers, which are bright-red outside and yellow within.

All the sorts are propagated by layers or by cuttings. The plants produced from cuttings are the best rooted, and should be done in September. Each cutting should have four joints and one bud at the bottom.

The honeysuckle loves almost any soil, provided it be not too dry. See Rhododendron.
HONEYSUCKLE, FRENCH (Hedysarum). Almost all the species of this genus are very handsome flowering plants, producing racemes of very beautiful pea flowers, particularly adapted for borders or rock-work. Miller mentions nineteen sorts. The greater number are peripherals. The most general species in English gardens is the H. coronarium, which blooms bright-red flowers, and a variety of it, which blooms white flowers, both flowering in June and July. They are propagated by sowing seed in the spring in light garden mould, and transplanting the young plants into their destined places in autumn. The herbaceous kinds are increased by dividing the roots. The horny part which covers the feet of many valuable quadrupeds. It is either cloven, as in cattle, or entire, as in the horse. In the horse it is that portion of the foot which is composed of the crus or wall, the bars, the sole, and the horny frog. There is no frog in the foot of cattle, nor are there the provisions for the expansion and elasticity of the foot which we admire in the horse. There is a laminated connection between the hoof of the ox, and the sensible parts beneath, as in the horse; but the horn plates of the hoof, and the fleshy ones of the substance which covers the coffin-bone, are not so wide and deep, and therefore the attachment between the hoof and foot is not so strong. The hoofs of cattle are used for making starch and Prussian blue, as they will not make glue or soap like the heels. (Cattle, p. 568; The Horse, p. 281.)

Hoop-Ash. See Hackberry.

HOOVE. See Cattle, Diseases of.

HOP (Humulus lupulus). This is a well-knownumber, supposed to be indigenous to England, plants of it being found in hedgerows and waste places. The ancients were not acquainted with the hop. It is mentioned by the Arabian physician Mesue, who lived about 845; and it was used for beer in Flanders in 1500. The female flowers, indeed, have been long used in many parts of Europe for the purpose of imparting a flavour to beer. It was not, however, cultivated in England for this purpose until about the year 1525; and as the Reformation was then in progress, the introduction of the hop is perpetuated by the following doggerel:

\[ \text{Hops, beerey, pickeral, and beer} \]
\[ \text{Were brought into England in one year.} \]

In 1528 the parliament was requested to prohibit its use, as an unwholesome weed that would spoil the taste of beer. It is mentioned for the first time in 1552 in the statute-book, in the 5 Edward VI. c. 5 (repealed 5 Eliz. c. 2); an act directing that land formerly in tillage should again be so cultivated, but excepting, amongst other ground, "land set with saffron or hops"; and down to the year 1693 hops were imported from Flanders in considerable quantities. In 1578 Reynold Scott published a curious little work on the cultivation of the hop, which is now rare: it was entitled, "A Perfitte Platforme of a Hoppe Garden," in which the directions for the cultivation of the hop are given with considerable care.

The chief counties in which the hop is now cultivated in England, are those of Kent, Sussex, Surrey, Worcester, and Essex; but the hop-gardens of these counties are only situated in particular portions.

The hop plants delights in a rich loam, or calcareous sand; and when these are situated on a calcareous bed, the plants will continue to flourish for many years; but otherwise ten or twelve years is about the limit of their continuance in perfection. Under favourable circumstances, as on the Kentish ragstone, the roots of the hop plant extend in some instances to a depth of eight or ten feet. The hop plant is usually raised from cuttings in the spring. "In the early part of the spring," says Mr. Lance, "the root or stumps: cut from the old stump of the last year's bine, which will have two or more buds; the crown of the root is then cleared, and these old stumps are cut off, or most part of them, the hole covered up, and the crown of the root throws up additional shoots to be tied up the poles. The plant is therefore said to have an annual stem, but a perennial root. The cuttings, or old stumps, are bedded for a season, to make roots the best way they can from the edge of the cutting: the plant being exceedingly tenacious of life, every portion of the stumps which has a bud will grow and throw out roots from the extremity of the woody cutting; they will make a circle of roots when healthy, and throw up bine from the eyes or buds at the surface of the ground, and other roots will issue from under the eyes. The shoots of the former year that may have become covered with earth will make plants as layers, throwing out many fibrous roots before they are cut off from the stump or crown. This is often the most successful method of obtaining plants, although it may in some measure weaken the old root; but the layerget the plants a year more forward, as the roots are already formed when the plant is taken from the old stock; but if all the supernumerary shoots are cut off after the principal ones are well up the pole, then there can be no suckling plants formed. There are several varieties of the hop," adds Mr. Lance, "named according to the colour of the bine, the hanging of the fruit, or local circumstances. The grape bine begins to bud from the hanging of the strobiles; the cluster being close together, like a bunch of grapes. Those named from the bine are the green, the white, the red. Others are named from places, as the Canterbury grape, the Farnham bell, the Mayfield grape; and some few are named from the persons who have raised them from seed, as Williams's white bine, at Farnham, being first raised by a gentleman of that name at Badshot Place, about the year 1700. This is the variety now principally cultivated at Farnham, and may be said to be one of the causes which make that place so famed for hops, they being purchased with avidity by the brewers of the west of England."

The qualities of the hop regarded by the dealers are the colour, scent, seed, and glutinous touch. The colour, which should be a light green, is attained either by a very careful and early picking, or by exposure the hops when they are drying to the action of fumes of sulphur. By exposure to the air, however, the
natural brown colour of the hops thus treated returns; and hence the Farnham hops are often preferred by the brewers of pale ale, because the colour is not apt to alter.

About 60 to 100 bushels of the picked hops are required for a cwt. of dried hops in the bag; but this varies with circumstances. When there is an abundance of plump, well-formed seed, from 40 to 70 bushels will form a cwt. A bag of hops will weigh about 23 cwt., and a Kent pocket about 14 cwt. The produce of an acre of hops will sometimes amount to 24 cwt., but the average is about 10 cwt. The hop plant is subject to many diseases, to the attacks of caterpillars and other insects, to mildew, and to a variety of atmospheric influences, which renders it ever the sport of the weather, and occasions the proverbial uncertainty of the crop.

In the culture of the hop, a deep soil is preferable, and many powerful fertilizers may be had advantage of. There is, perhaps, 100 per cent., which delights more in those of an oily nature than the hop. The Kentish growers of the valley of the Medway successfully employ large quantities of sprats, for which they readily give 10d. per bushel. They use from 40 to 60, or more, bushels per acre. Other planters employ woollen rags, chopped into small pieces, from 1 to 2 tons per acre. They last for 2 years. These cost about 5s. per ton. Salt, also, is an excellent addition, in conjunction with these, at the rate of from 10 to 15 bushels per acre.

The plants are usually placed on hills, at the distance of 5 or 6 feet, and this is usually done early in the spring, about the end of March. The first year’s poles may be about 6 feet in length, but twelve feet poles are afterwards needed. Two or three of these are commonly placed on a hill: they are generally set in the ground in the end of April. About 500 fresh poles are usually required per acre, to keep up the stock of poles, and supply the place of those broken or otherwise destroyed.

The ground in hop gardens can hardly be too much stirred over. The drying of the hops is effected soon after they are picked. For the despatch of drying, a thickness of from 1 to 2 feet of hops are placed on the kiln-floor, and a fire of culm or Welch coal, coke, charcoal, or other material that gives out no smoke, is made in an open fireplace, with only a perforated hood over it; or, if the kiln-floor is encased, and the smoke-flue is made to pass round the building, any firing may be used; but the nearest and cleanest method is by passing hot water through pipes, close beneath the drying-floor. About 100 to 200 bushels are commonly dried at once in the ordinary-sized hop-kilns. Considerable quantities of sulphur are sometimes added to the fire, sometimes as much as a cwt. to a ton of hops. About 98 to 112 degrees of heat is that commonly employed in the drying, and the cost of the process is about 1s. per cwt.

In bagging the hops, great care is requisite to treat them as close as possible; for the more completely the air is excluded, the better the hops will keep.

The dried hop has been analyzed, and found to contain lupulin, a bitter principle, _opism_, a

fatty astringent matter, gum, _chlorophyle_, and _ligulin_. In the grains of the lupuline a volatile oil is deposited. The salts of iron, gelatin, chloride of barium, and oxalate of ammonia, cause precipitates in the decoction of the hop. As a medicinal agent, hops display tonic and narcotic properties. A pillow of hops is supposed to be a good soporific, and was obtained for George III. when a lunatic. The extract has been found to allay pain; but, after all, it is better as an adjunct to beer than as a medicine.

In England, the expense of 1 cwt. of hops, if purchased on the poles (says Mr. Lance,) may be thus stated:—

| The duty | - | - | - | 0 18 8 |
| Picking | - | - | - | 0 10 8 |
| Bags | - | - | - | 0 1 0 |
| Drying | - | - | - | 0 5 0 |
| Bagging | - | - | - | 0 2 0 |
| Cartage | - | - | - | 0 2 0 |
| Sale | - | - | - | 0 1 0 |

1 18 9

The following are the expenses and produce of 4 acres of hop ground in Mid-Kent in 1836:—

| Rent and taxes on 4 acres, at 46s. | - | - | - | 9 0 9 |
| Culture labour, at 50s. | - | - | - | 10 0 0 |
| Repair of poles | - | - | - | 4 0 0 |
| Dunging, at 9s. per cwt. | - | - | - | 23 0 5 |
| Picking 3,423 bushels, at 7s. per bu. | - | - | - | 3 12 0 |
| Drying, labour only | - | - | - | 5 1 0 |
| 39 pockets, making, marking, sifting, and drying, at 1s. 2d. | - | - | - | 2 5 6 |
| Pole pullers, measurer, and expenses | - | - | - | 4 16 0 |
| Pocket cloth | - | - | - | 6 10 6 |
| Coal | - | - | - | 0 17 6 |
| Charcoal | - | - | - | 0 17 6 |
| Sulphur and lime | - | - | - | 0 0 0 |
| Rent of kiln | - | - | - | 5 14 0 |
| Interest on first years’ expenditure | - | - | - | 4 0 0 |
| Duty on 61 cwt., at 18s. 8d. | - | - | - | 59 14 0 |
| Title | - | - | - | 4 0 0 |

147 10 6

The produce, 64 cwt., at 61. 10s. 416t.

The average produce of hops from 1807 to 1836, as shown in a table from the work of Mr. Lance on the hop, is 53 cwt. per acre, the highest product in one year having averaged for the crop 12 299 cwt. in 1808, and the lowest only 37 26 192.

The number of acres devoted to the cultivation of the hop has long been steadily on the
HORDEIN.

increase since 1693; when they were first success- fully cultivated in Kent; in 1807, it was found that the hop-grounds throughout England amounted to 38,218 acres; these had increased to 46,293 acres in 1817, to 49,485 in 1827, and to 56,323 acres in 1837; they had decreased however in 1839 to 52,365.

Hops are extensively and advantageously cultivated in some parts of the United States. Gurdon Avery, in the village of Waterloo, Oneida county, N. Y., raised in 1842, on 12 acres of land, 29,937 lbs. of hops.

The hop is also well known as a garden plant. It blows its flowers from June till August, and is propagated by seed and by dividing the roots. It likes a deep loamy soil, and is valuable as an ornamental climber over temporary arbours, trellis, &c. In summer, as its leaves are very large, and make a fine shade. The "white bind" and the "gray bind" are the best sorts for this purpose; they succeed each other.

The young shoots of the hop are eaten as a depurative; the flowers, besides their bitter narcotic qualities, are diuretic and sedative.

HORDEIN. A modification of starch, which, according to Proust, constitutes about 55 per cent. of barley-meal.

HORDEUM. The barley-grasses. Besides the species of cultivated barley enumerated in the article under that head, there are three indigenous species which grow wild in England.

Hordem maritimum. Sea-barley, or squirrel-tail grass. This species is annual in its habit, and grows in pastures and sandy ground near the sea. It most resembles H. maritimum in general habit, but is on the whole rather smaller, and more glaucous. The awns are all rougher, with minute briskly teeth. The plant is not of common occurrence, although it abounds in the isle of Thanet. (Eng. Flor. vol. i. p. 179; Hort. Gramm. Web.)

HOREHOUND, WATER. One of the names of the common gipsy-wort (Lycopus Europaeus); which see.

The plant called by this name in the United States, is L. sinuatus, which frequents the low grounds of Pennsylvania and other Middle States. (Flora Cestrica.)

HOREHOUND, WHITE (Marrubium vul- gare, from marrob, a Hebrew word, signifying a bitter juice; in allusion to the extreme bitterness of the plant). This species grows in rubbish by road-sides, in dry waste grounds, and on commons, flowering from July to September. The stem is bushy, branching from the bottom, bluntly quadrangular, clothed with fine woolly pubescence. The shape and size of the leaves varies; the flowers are white, in dense convex whorls. The whole herb has a white or hoary aspect, and a very bitter, not unpleasantly aromatic, flavour. Its extract is a popular remedy for coughs and asthmatic complaints; hence also the celebrity of horehound-tea among the common people. Bees collect honey from the flowers; but the herb is not eaten by any of the domestic animals.

Any common soil will suit these plants, and they are readily increased by divisions of the roots, or by seeds. (Eng. Flor. vol. iii. p. 103; Paxton's Ed. Dict.)

HORN. A hard substance, growing on the heads of various animals, which partakes of the chemical nature of the cartilaginous part of bone; it consists chiefly of albumen, with some gelatin and a trace of phosphate of lime.

The horn of the ox is composed of an elongated bone, covered by a hard coating, originally of a gelatinous nature. Its base is a process or continuation of the frontal bone, and it is, like that bone, hollow, and divided into numerous compartments or cells, all of them communicating with each other,
and lined by a continuation of the membrane of the nose. The bone of the horn is exceedingly vascular, and hence, when broken, the hemorrhage would equally be more bleeding from the amputation of a limb. The rings on the horns of cattle have been considered as forming a criterion by which to determine the age of the ox. At three years old the first distinct one is usually observed; at four years old, two are seen; and afterwards one is added each succeeding year. Thence was deduced the rule, that if two were added to the number of rings the age of the animal would be given. These rings, however, are perfectly distinct in the cow only; in the ox they do not appear until seven years old, and they are often confused; in the bull they are either not seen until five, or they cannot be traced at all. As a criterion of age, this process of nature is far too irregular for any certain dependence to be placed upon it, and the rings are easily effaced by a rasp.

The length of the horn—whether classed as long horns, short horns, or middle horns—now forms the distinguishing character of the different breeds of cattle. The oxen of the northern part of central Africa, although smaller than the majority of the English cattle, have horns that are nearly four feet in length, and will contain more than ten quarts. The Burmese oxen, which are much larger, have singular horns of a half spiral form, very soft, the pair together scarcely weighing 4 pounds; yet Captain Clapperton tells us, they are 3 feet 7 inches in length, 2 feet in circumference at the base, and 1 foot 6 inches midway towards the tip. Some of the true Arnee buffaloes at Bengal, and the Abyssinian cattle, have also enormous horns. The horns of cattle are applied to a variety of purposes; for making combs, knife-handles, the tops of whips, substitutes for glass in lanterns, glue, and the refuse chippings are used as manure.

The Iceland sheep sometimes carry five or six horns. (Yovati on Cattle, p. 278-283.)

HORNBEAM (Carpinus betulus, from the Celtic ear, wood, and piùda, head, the wood being fit for the yokes of cattle). A rigid tree of humble growth, patient of cropping, and well suited for hedges and for divided walks in gardens of the old style, some of which may still be seen attached to several old English mansions. In English fashion has entirely swept away the hornbeam, which composed the labyrinth, the maze, the alleys, the verdant galleries, arcades, porticoes, and arches of our forefathers, and which formed the leafy walls that divided their stately gardens into stars, goose-foot avenues, and devices as numerous as geometrical figures are various. When standing by itself and allowed to take its natural form, the hornbeam makes a much more handsome tree than most people are, aware of, growing from 12 to 30 feet high. It is found in woods and hedges, on a meager, damp, tenacious soil, and makes a principal part of the ancient forests on the north and east sides of London, as Finchley, Epping, &c. The wood is, as Gérarde says, of a horny toughness and hardness; the bark smooth and whitish or light gray. Leaves resembling those of an elm, but smooth, doubly serrated, pointed about two inches long, plaited when young, having numerous, parallel transverse hairy ribs.

Young trees are raised from seeds or layers without difficulty. It is known by different local names, such as the hard beeme tree, the horse, or horn beeche tree, &c. The leaves of the hornbeam afford a grateful food to cattle, but no grasses will grow under their shade. The wood burns like a candle, is much employed by turners, and is very useful for various implements of husbandry, being wrought into cogs for the wheels of mills, presses, &c. which are far superior to those made of yew.

There are two trees in the United States which go under the common appellation of hornbeam, namely, the water beech (Carpinus Americana of Michaux, Betulus Virginica of Marsh,) and the hop hornbeam, more generally known by the name of ironwood (the Ostrya Virginica of Darlington, and Carpinus ostrya of Michaux and others).

The water beech is the only known species of the Carpinus genus in the United States. It is found along the margins of rivulets in the Middle States, where it attains the height of only 10 or 20 feet, with 2 to 5 inches in diameter, irregularly and obtusely ridged, and sulcate, often branching from the root. It bears a broad ovoid nut, somewhat flattened, smoothish, and dark brown.

The ironwood, or hop hornbeam grows from 20 to 40 feet high, and 4 to 10 inches in diameter, with a brown, roughish, slightly fissured bark, and slender branches. It bears a nut seated in the bottom of a sac, 3 or 4 lines in length, somewhat compressed, smooth, shining, of a pale olive colour, with a leaden tinge. This tree is of very slow growth, and its wood, as its name implies, is very hard, which adapts it to the various useful purposes enumerated in the description of the English hornbeam.

HORN BUG. A kind of beetle. The largest of these beetles, in the New England States, was first described by Linnaeus under the name of Lucanus caprulus, signifying the young roebuck; but here it is called the horn bug. Its colour is a deep mahogany brown; the surface is smooth and polished; the upper jaws of the male are long, curved like a sickle, and furnished internally beyond the middle with a little tooth; those of the female are much shorter, and also toothed; the head of the male is broad and smooth, that of the other sex narrower and rough with punctures. The body of this beetle measures from one inch to one inch and a quarter, exclusive of the jaws. The time of its appearance is in July and the beginning of August. The grubs live in the trunks and roots of various kinds of trees, but particularly in those of old apple trees, willows, and oaks.

Several other and smaller kinds of stag-beetles are found in New England, but their habits are much the same as those of the more common horn bug. (Horus.)

HORNED-POPPY (Glauconium, from glauke, alluding to the hoary grey colour of the plants). A genus of very pretty annuals, or biennials, some of which are particularly handsome in the flower borders of the garden, where they
flower and ripe seed in abundance, which has only to be sown in the open border. The following are the English species.

1. Yellow horned-poppy (G. haleum). This is a biennial, growing wild on the sandy seacoast, producing golden-yellow flowers in July and August.

2. Scarlet horned-poppy (G. phaeniceum). This is very rare, or, as Smith observes, perhaps doubtful native. It is annual in habit, the root is slender, stem erect, a foot high, round, even, and quite smooth; leaves dark green, twice or thrice pinnatifid; flowers of a brilliant violet blue, very splendid, but extremely fugacious, somewhat larger than the last; pods 2 or 3 inches long, cylindrical, more or less clothed with bristly prickles. (Eng. Flor. vol. iii. p. 61; Paxton's Ed. Diet.)

HORNET (Vespa crabro). A well-known fierce insect, which is about one inch in length, and builds its nest in hollow trees. The sting of the hornet is severe, and occasions a considerable tumour, accompanied with intense pain; for the mitigation of which, there is no better remedy than sweet oil, or honey water immediately applied to the place. Hornets are very dangerous enemies to bees, which they attack and consume entirely, except the wings and feet: they are also very destructive to fruit.

The American hornet is the Vespa maculata of naturalists. Instead of building their nests in hollow trees, the American hornets are natural paper-makers, and manufacture water-tight nests of paper, which they construct around the branches of trees or shrubs where they appear as large globes, sometimes a foot or more in diameter. The material of these nests consists of the fibres of wood, prepared by the insects, and wrought into a substance very similar to common brown paper made of rags. Like others of the wasp family, the American hornet is a depredator upon fruit, and comes about harvest in search of ill-timed abundance.

HORNWORT (Ceratophyllum, from keras, a horn, and phyllos, a leaf: the petals are cut so as to appear like a stag’s horn). These are uninteresting water plants, thriving in any pond, and easily raised from seeds. The common hornwort (C. demersum) is abundant in ditches and fish-ponds; the herb floating entirely under water, dark green, copiously branched, 2 or 3 feet long, densely clothed with white or spreading forked leaves, eight in each whorl, and axillary, solitary, sessile, pale green flowers. The fruit armed with two spreading lateral spines. There is another indigenous species the unarmed hornwort (C. submersum), which is a mere plant, and the fruit is destitute of spines.

There are two species of this plant found in the United States. One of them (Ceratophyllum demersum) is described by Darlington as found in the waters of the Schuylkill, Brandywine and tributaries; the other (C. submersum) is described by Messrs. Nuttall and Eaton.

HORSE, THE. The genus Equus, according to modern naturalists, consists of six different animals,—viz. the Equus caballus, or horse; E. hemionus, the dzigghtai; E. asinus, the ass; E. quagga, the quagga; E. zebra, or mountain zebra; and E. burchelli, the zebra of the plains. It is only of the first that I shall have to treat in this article.

Horse, the. This noble animal, there is little doubt, is a native of the warm countries of the East, where he is found wild in a state of considerable perfection. It is there that we find the barb and the Arab, noble races of horses that have long mainly contributed to improve the present English race-horse, until he has arrived at his present state of unequalled perfection. The use of the horse, both as a beast of burden, and for the purposes of war, early attracted the attention of mankind. Thus the Canaanites are recorded as having gone out to fight against Israel with many horses and chariots. (Joshua ii. 4.) And 1650 years b. c., when Joseph proceeded with his father’s body into Canaan from Egypt, there accompanied him both chariots and horsemen. (Gen. xix.) They were fed in those days on barley (1 Kings, iv. 28): and 150 years afterwards, the chariots of Egypt are described as being exceedingly numerous. The horse was early employed on the course. 1450 years b. c. the Olympic Games were established in Greece, at which horses were used in the chariot and other races.

Preserved from the flood waters in the ark, the first breed of horses must have proceeded from the neighbourhood of Mount Ararat; but whether the present stock was derived from Asia or in Africa is an inquiry which we have no means of deciding. Equally ineflectual are all the attempts which have been made to decide as to which variety of the horse constitutes the original breed; while some contend for the barb, others prefer the wild horses of Tartary. It is certain, however, that so late as the seventh century there were but few horses in Arabia; even now the breed is much more limited in number, according to Burckhardt, than is commonly supposed. He remarked, in a letter to Professor Celsius, "It is a mistaken idea that Arabia is very rich in horses; the breed in that country is limited to the extent of its fertile pasturing districts; and it is in these parts only that the breed prospers; while the Bedouins, who are in possession of poor ground, seldom possess any horses. We therefore see that the tribes richest in horses are those who dwell in comparatively the fertile plain of Mesopotamia, on the borders of the Euphrates, and in the Syrian desert. It is there that the horses can feed for several spring months upon the green grass and herbs of the valleys and plains, produced by the rains, which seem to be an absolute requisite for its reaching to its full vigour and growth." The care with which the Arabs tend their horses is prover-
HORSE.

bial. "The Bedouins," adds Dunkirdt, "when a horse is born, never let it drop down to the ground, but receive and keep it for several hours upon their arms, washing it, stretching and strengthening its limbs, and hugging it like a baby." (Quart. Journ. of Agr. vol. vii. p. 677.) None were found either on the continent or on the islands of the New World. And yet the large droves of wild horses which have descended from the two or three mares and stallions left by the early Spanish voyagers, and which now abound in the plains of South America, prove very clearly that the climate and the soil of the New World are not adverse to the propagation of the wild horse.

"The horse," says Professor Low (Illustrations of the Breeds of the Domestic Animals, part ix.), "is seen to be affected in his character and form, by the agencies of food and climate, and it may be by other causes unknown to us. He sustains the temperature of the most burning regions; but there is a degree of cold at which he cannot exist, and he approaches to this limit, his temperament and external conformation are affected. In Iceland, at the arctic circle, he has become a dwarf; in Lapland, at latitude 65°, he has given place to the reindeer; and in Kamtschatka, at latitude 55°, he has given place to the dog. The nature and abundance of his food, too, greatly affect his character and form. A country of heaths and nutritious herbs will not produce a horse so large and strong as one of plentiful herbage. The horse of the mountains will be smaller than that of the plains; the horse of the sandy desert than of the watered valley."

Leaving, however, these interesting, but for this work too extensive, researches, I propose to direct my attention to the English breed of horses, and more especially to those which come particularly within the farmer's province.

From a very early period there appears to have existed in England a powerful, active, useful, and numerous breed of horses. Caesar, perhaps with the natural inclination to a conquest which characterized his defeated enemies, gives a very lively account of the horses used by the early Britons in their war chariots; which, armed with iron scythes affixed to their axletrees, were driven furiously and destructively amid the ranks of their enemies. And if it be true, that when Cassibeluanus had disbanded the chief portion of his army, he yet retained 4000 war chariots to harass the foraging parties of the Roman army; the supply of good horses able to work these heavy war chariots with sufficient speed over the open country, and bad roads of that period, must have been very considerable.

Of such imperfect materials is constituted all the accounts in our possession, of the native breed of English horses. That they were valuable, is proved, amongst other things, by the fact, that the Roman generals carried many of them to Italy. The improvement of the breed was an object of the early Saxon princes of England. Athelstan imported several German, Swedish, and Danish horses, and by an act (930) prohibited the exportation of those bred in England, a decree, which of itself proves that they were then in demand abroad. It is supposed that oxen were, in his days, solely used for the plough; there is no early record of the horse being used for such a purpose. The first notice of a horse being employed in agriculture, is in tapestry of Bayeux (woven in 1066), where one is depicted drawing a harrow.

With William of Normandy came many Spanish horses. His army was furnished with a powerful cavalry, to whom he might well attribute his hard-fought victory of Hastings.

In 1191, we have the first notice of an Arabian horse being in Great Britain; for in that year, I find that Alexander I. of Scotland presented one to the church of St. Andrews. King John procured from Flanders 100 stallions, and is to be gratefully remembered for other efforts to improve the English breed of horses. Edward II. and Edward III. also imported horses from Lombardy, France, and Spain. Henry VIII. did all he could to encourage the breed of race-courses, which now established at Chester and at Stamford. But it was not till the time of James I. that the modern system of racing, under certain rules and regulations, commenced, and a peculiar breed of race-horses began to be formed; for previous to that time fast horses of all breeds ran in the same race.

This noble breed of race-horses, which now excels in beauty, speed, and endurance that of all other nations, has been gradually formed by the introduction of the best blood of Spain, of Barbury, of Turkey, and of Arabia. It would be a grateful task to follow the English race-horse through his entire history, to trace his progress by gradual yet steady degrees towards perfection, his generous properties, his contests, and his triumphs over the best horses of Arabia, of Persia, and of the New World; out-footing the fittest, and in endurance excelling all that the proud nobles of Russia could produce of the best and most celebrated Cossack horses of the banks of the Don. But in a work devoted to agriculture, my attention must be more directed to those valuable breeds of horses generally employed by the farmer.

The Arabian horse is represented in Pl. 13, a; the English racer, b, reduced, from Professor Low's splendid work on British animals. The English improved hackney, d.

The Cart Horse.—Of this description there are several varieties, the principal of which are the Cleveland, the Clydesdale, the Northamp- tonshire, the Suffolk punch, and the heavy black or dray horse.

The Clydesdale is a valuable breed of cart-horses, bred chiefly in the valley of the Clyde (hence their name). They are strong and hearty, have a small head, are longer necked than the Suffolk, with deeper legs, and higher carcasses. Pl. 13, h.

The Suffolk Punch is a very valuable breed of horses, especially for farms composed of soils of a moderate degree of tenacity. They originated by crossing the Suffolk cart mare with the Norman stallion. Pl. 13, g.

"The true Suffolk," says the author of the Lib. of Useful Know. (The Horse," p. 38.), "like the Cleveland, is now nearly extinct. It stood from 15 to 16 hands high, of a sorrel colour 3 H 637
HORSE.

was large-headed, low-shouldered, and thick on the top, deep, and round-chested, long-backed, high in the croup, large and strong in the quarters, full in the flanks, round in the legs, and short in the pasterns. It was the very horse to throw his whole weight into the collar, with sufficient activity to do it effectually, and hardihood to stand a long day's work. The present breed possesses many of the peculiarities and good qualities of its ancestors. It is more or less inclined to a sorrel-brown: it is a taller horse, higher, and finer in the shoulders, and a cross with the Yorkshire half or three-fourths bred. The excellence, and a rare one, of the old Suffolk (the new breed has not quite lost it) consisted in nimbleness of action and the honesty and continuance with which he would erect himself at a dead pull even until he dropped.

The heavy black horse is chiefly bred in Lincolnshire, and the midland counties. Pl. 13, c. These are commonly sold by the breeders at two years old to the farmers of Surrey, and other large metropolitan counties, who work them till they are four years old, and then sell them to the London merchants for brewers' drays, and other heavy carriages. "This kind of horse," says the same excellent authority I have just quoted, "should have a broad chest, and thick and upright shoulders (the more upright the collar stands on him the better), a low forehead, deep and round barrel, loins broad and high, ample quarters, thick fore-arms and thighs, short legs, round hoofs, broad at the heels, and soles not too flat. The great fault of the large dray horse is his smoothness. This is so much in the breed, that even the disciplined ploughman who would be better pleased to get through an additional rood in the day, cannot permanently quicken him. The largest of this heavy breed of black horses are used as dray horses. The next in size are employed as wagon horses; and a smaller variety, and with more blood, constitutes a considerable part of our cavalry, and is likewise devoted to undertakers' work." (Lib. of Useful Know. p. 46.)

"The dray horse," says Mr. Wilson, "probable results from a fine carriage horse, possessed of a certain portion of blood, and a very strong well-formed mare of the country breed. The gigantic proportions and immense powers of these horses are only equalled by their intelligence and docility. It may safely be said that this breed of horses is not to be paralleled on the face of the earth." (Quart. Journ. of Agr. vol. ii. p. 34.)

Besides these valuable kinds of English draught horses, there are a variety of mongrel breeds employed by the farmers, especially in the neighbourhood of London, and other large towns, which it is needless to name, and difficult to describe. Aged or lame cab horses, the refuse of the London hackney coaches, &c. may all be seen drawing the small farmers' teams in the neighbourhood of London. An English draught mare is represented at Pl. 13, f. reduced, from Stephens' Book of the Farm.

Too little attention is generally paid, in fact, to the breeding of superior cart horses by the farmer. The soil and the food which the district produces, has commonly more influence upon the size of the animal than the choice of the mare or the stallion; and although by the exertions of the Highland, and other Agricultural Societies, the breed is now considerably improved, yet still much more remains to be effected in this way. The Ayrshires Agricultural Association, at a late meeting, determined upon the purchase of a Flemish stallion, for the purpose of improving the breed in Scotland, the Society being convinced that there is a much better breed of draught horses in Flanders than in any part of Great Britain.

"The most important circumstance," says a well-known author, "which influences the profits of the farmer, is the cost of his team and the wages of his labourers. These vary in different situations. In some parts of the country the horses are pampered and kept so fat that they can scarcely do a day's work as they ought. In others they are overworked and badly fed. Either extreme must be a loss to the farmer. In the first case the horses cannot do their work, and consume an unnecessary quantity of provender, and, in the other, they are soon worn out; and the loss in horses that become useless, or die, is greater than the saving in their food, or the extra work done by them. A horse properly fed will work 8 or 10 hours every day in the week, resting only on Sundays. By a judicious division of the work of the horses, they are never over-worked, and an average value of a day's work is easily ascertained. Thus, in a well-regulated farm, will be found much less than the common valuations give it."

The labour of a horse is commonly reckoned equal to that of 5 men; he works, however, only 8 hours, while a man works 10. It has often been asserted that the powers of endurance of a man are considerably greater than that of a horse; and in a hurdle race at Ipswich, in 1841, between a capital hunter carrying 10 stones, and Townshend, a celebrated drayman, over 16 miles of ground, and 100 hurdle leaps, the horse was easily beaten. In a second trial, however, the horse came off the winner. The power of a horse in pulling seldom exceeds 144 lbs.; but he will carry from 500 lbs. to 1000 lbs. The power of a horse in pulling, if equal to 144 lbs. at a rate of 2 miles an hour, would be reduced to 64 lbs. at 4 miles an hour, and to 36 lbs. at 6 miles. In wheel carriages, on level roads, a horse will draw easily about 15 times the power exerted. A horse, in a single-horse cart, seems capable of drawing his load to the greatest advantage, and of late several improved single-horse carts have been suggested. (See Carts; and Journ. of Roy. Agr. Soc. vol. ii. p. 73.) The single-horse carts, both of London and Liverpool, convey enormous weights over the paved streets; and at Paris a single horse draws 2 tons. The carriers between Edinburgh and Glasgow, in carts weighing 7 cwt., convey a ton of goods 22 miles a day with one horse. The carriers of Normandy, with 4 horses, in 2-wheeled carts, weighing 11 cwt., convey from
British Horses
HORSE.

The Hunter. Pl. 13, c. It has been said that the hunter should be rarely under 15 or 16 hands high; below this he cannot well stand over his work, and above this he is apt to be long-legged and awkward at his work. With the increased speed of the hounds, and by the enclosures increasing the powers of the country to retain the scent, the speed of the modern hunters is much greater than that of the olden time, when with slow hounds, and strong, active horses, the country gentlemen had their "meets" at break of day, and continued the chase for hours. Those were scanty, but now, in fact, generally agreed that the modern hunter should be at least three-quarters bred. Many prefer the thorough-bred horse, especially if he can be procured with sufficient bone. The properties which a good hunter should possess, are thus described in the Library of Useful Knowledge (The Horse, p. 51): "He should be light in hand; for this purpose his head must be small, his neck thin, and especially thin beneath his crest, firm and arched, and his jaws wide. The head serves as a "meeter" at break of day, and continues the chase for hours; there is weight generally in it; it will form that angle with the neck which gives a light and pleasant mouth. Somewhat of a ewe-neck, however it may lessen the beauty of the race-horse, does not interfere with his speed, because more weight may be thrown forward, and consequently the whole bulk of the animal more easily impelled; at the same time the head is more readily and perfectly extended, the windpipe is brought almost to a straight line from the lungs to the muzzle, and the breathing is freer. Should the courser, in consequence of this form of the neck, bear more heavily on the hand the race is soon over, but the hunter may be our companion and our servant through a long day, and it is of essential consequence that he shall not too much annoy and tire us by the weight of his head and neck. The forehead should be lofter than that of the racer. A turf horse may be forgiven if his hind quarters rise an inch or two above his fore ones. His principal power is wanted for behind, and the very loveness of the forehead may throw more weight in front and cause the whole machine to be more easily and speedily moved. A lofty forehead, however, is indispensable in the hunter, the shoulder as extensive as in the racer, as oblique, and somewhat thicker; the saddle will then be in its proper place, and will continue so, however long may be the run. The barrel should be rounder, to give greater room for the heart and lungs to play, and send more and purer blood to the larger frame of this horse; and especially more room to play when the run may continue unchecked for a time that begins to be distressing. A broad chest is an excellence in the hunter. In the violent and long-continued action of the chase, the respiration is exceedingly quickened, and abundantly more blood is hurried through the lungs in a given time, than when the animal is at rest. There must be sufficient room for this, or the animal will be blown, and possibly destroyed. The majority of horses that perish in the field are narrow-chested. The arm should be as muscular as that of the coursers, or even more so, for both strength and endurance are wanted. The leg should be deeper than that of the race-horse (broader as you stand at the side of the horse), and especially beneath the knee. In proportion to the distance of the tendon from the cannon or shankbone, and more particularly just below the knee, is the mechanical advantage with which it acts. A racer may be tied beneath the knee without perfectly destroying his power, but a hunter with this defect will rarely have stoutness. The leg should be neither longer than that of a race-horse, for higher action is required of him, that the legs may be cleanly and safely lifted over many an obstacle, and particularly that they may be well doubled up in the leap. The pastern should be shorter, and less slanting, yet retaining considerable obliquity. The long pastern is useful by the yielding resistance which its obliquity affords to break the concussion with which the race-horse, from his immense stride and speed, must come to the ground; and the oblique direction of the distal contribution to effect the same purpose. With this elasticity, however, a considerable degree of weakness is necessarily connected, and the race-horse occasionally breaks down in the middle of his course. The hunter, from his different action, takes not this length of stride, and therefore wants not all this elastic mechanism; he more needs strength to support his own heavier carcass, the greater weight of his rider, and to endure the fatigue of a long day. Some obliquity, however, he requires, otherwise the concussion of his shorter gallop, and more particularly of his frequently tremendous leaps, would inevitably lame him. The foot of the hunter is a most material point, for it is battered over many a flinty road and stone field, and if not particularly good, will soon be disabled and ruined. The position of the feet requires some attention in the hunter; they should, if possible, stand upright. If they turn a little outward, there is no serious objection, but if they turn inward, his action can hardly be safe, particularly when he is fatigued or over-weighted. The body should be short and compact compared with that of the race-horse, that he may not, in his gallop, take too extended a stride. This would be a serious disadvantage in a long day, and with a heavy rider, from the stress on the pasterns; and more serious efforts required when going over clayey, poachey ground in the winter months. The compact, short-strided horse will almost skim over the surface, while the feet of the longer-reached animal will sink deep, and he will wear himself out by efforts to disengage himself. The loins should be broad, the quarters long, the thighs muscular, the hocks well bent, and under the horse." (Ibid. p. 53.)

Galloways. A horse between 13 and 14 hands high is called a galloway. The name originated from a beautiful race of little horses once bred in Scotland, on the banks of the Solway Frith. The pure galloway was distinguished for its speed and stoutness, and was
remarkably sure-footed. Horses of this kind are very serviceable and useful; are capable of performing a great deal of light active work, and are rarely so high-priced as the larger horse.

**Ponies.** Of these there are an endless variety, both in fine shape and value. The Welch pony is perhaps the most beautiful of the class. He has a neat small head and barrel that is at once round and deep, good feet, short, strong joints, flat legs, with high withers. Some of the most beautiful ponies of England are of this breed.

The New Forests are commonly very ill-made, coarse, ragged, large-hipped, ugly animals, but active, enduring, hardy, and easily maintained upon very coarse food. The same remarks will pretty generally apply to those of Exmoor and Dartmoor in Devonshire.

Of the Scotch breeds, the Highland is the largest, and the most useful; those of the Shetland Isles, called in the north shielies, (Pl. 13, k,) range between 7½ and 9½ hands in height, are often small-headed, beautiful, good-tempered, and docile. They have short necks, long and thick shoulders, short backs, possess great strength, and will fatten upon the coarsest food.

The Irish Horse.—In the rich grazing districts of Roscommon and Meath, many large thoroughbred horses are reared, that were formerly distinguished for their large, coarse, ragged, rawboned appearance, but the breed has been very materially improved by the introduction of superior stallions and other means, so that now many of the Irish horses claim an equality with the best of those of England. The Irish horse is commonly beautiful, fiery, yet good-tempered, easily excited, of great endurance, and perhaps the best leaper in the world. The Irish Hunter is represented in Pl. 13, i, from Lowe's work on British animals.

**Feeding Horses.**—The best method of feeding horses, especially those belonging to the farm, is a question highly interesting to the farmer. Many are the substances employed for this purpose, such as oats, oatmeal, barley, bran, beans, peas, potatoes, turnips, carrots, parsnips, hay, sainfoin, clover, rye-grass, straw, grains, and sometimes oil-cake: bruised gorse or furze is excellent. The oats are best given when bruised, the potatoes should be steamed and mixed with chaff and salt; hay and straw are economically cut into chaff. In many of the stables about London, hay is never put into the rack. Thus in the stables of Hanbury and Truman, each horse is allowed per day 18 lbs. of cut hay and straw (one-eighth of the latter), 14 lbs. of bruised oats, and 1 lb. of bruised beans; half a pound of salt per week is also given; in summer the beans are withdrawn, and the oats increased. In France the daily rations allowed to the heavy cavalry horses are, oats 10 lbs., hay 10 lbs., straw 10 lbs. (“On the Norman Horse,” Quart. Journ. of Agr.)

Dr. Sully, of Wivel'scombe, some years since, gave the following statement of the different articles of food which his horses received to keep them in excellent condition. He, too, had no racks in his stables. (Ibid. vol. ii. p. 726.)

With 2 oz. salt for each class

The advantage of cooking the food for horses has been advocated by Mr. Dick, *Ibid.* vol. iii. p. 1024; and in many cases is a practice highly to be commended. An apparatus for steaming food for horses with an engine is given, *Ibid.* vol. vi. p. 33; and Mr. Fisher details the mode of feeding them with potatoes, *Com. Board of Agr.* vol. iv. p. 395. A machine for bruising grain for horses is described in *Quart. Journ. of Agr.* vol. v. p. 100. The number of horses of all kinds in England is estimated by Mr. M'Culloch, to be from 1,400,000 to 1,500,000, which, at an average value of from 12½ to 15½, makes their total value from 18,000,000l. to 22,500,000l. In 1832, the riding-horse duty was paid for 182,878 horses. (*Com. Dict.*) It appears from this statement accompanying the census of the United States in 1840, that the number of horses and mules in the Union was 4,333,669.

The Wild Horse.—The horse is still found wild in Africa, in Tartary, and in America, in the Southern continent, of which last country they are said to be sometimes found in droves of 10,000. It is here that they seem to act both in self-defence, and for the attack of their enemies, with a subordination and union of purpose that is not a little curious. It seems that they have some chief, who is their courageous leader in the onset, the first to direct their retreat. They close, at some intelligible signal, upon their enemies, and trample them to death. These, amongst the natives of America, are neither very numerous nor dangerous. The leopard, tiger, and lion of the New World are very inferior animals to their namesakes of the olden continent. Man is their greatest enemy; they are hunted and captured by the Guachos with their lassos, or even killed for their skins and flesh, in considerable numbers. These wild American horses are not particularly fast, but they can endure great fatigue, and, when once tamed, are exceedingly docile. Other wild horses are found in various parts of the world, but nowhere in a state of nature does he equal the size, the form, the speed, or the strength of the domesticated horse.

For an interesting account of the wild horses of South America, see the *Farmer's Register*, vol. ii.

Good keep and good management, indeed, strangely improve the appearance of even the
HORSE.

naturally poorest breeds. The ponies of Shetland, or the still more diminutive steeds of China, when bred on rich English pastures, rapidly increase in size. The horses of Arabia do the same.

In the extensive territory of the United States, several breeds of horses are found, the characteristics of which are widely different.

The Canadian. This is one of the principal races found in the Northern States, and is generally considered of French or Norman descent, many of the characteristics of which are retained.

The Morgan horse. Perhaps the very finest breed of horses in the United States, when general usefulness is taken into consideration, is what is commonly known in the Northern and Eastern States, as the Morgan horse. This breed is distinguished by its activity, united with strength and hardiness. Its size is moderate, and though not often possessing the fleetness which recommends it to the sportsman, it has enough speed to entitle it to the appellation of a fast traveller. Their usual height is from 14 to 15 hands, colour bay, make round and rather heavy; with lean heads, broad and deep chests, the fore-limbs set wide apart, legs clean and sinewy, short, strong back, with that projection of the ribs from the back, which is a sure indication of great development of lungs, and consequently of great wind and bottom. For saddle, draught, and other useful purposes, the Morgan horses bred in Vermont, and in all the Eastern States, including the Northern and Western part of New York, are so much prized as to command much higher prices in the principal cities of the Atlantic States than horses from other parts of the Union.

This fine race is generally believed to have originated in the northern part of Vermont about the year 1804, from a mixture of the French horse from Canada, with New England mares. The breed is sometimes known by the name of the Goss horse. Some of the celebrated American trotters are of the Morgan breed.

Conestoga horse. This horse, which is found chiefly in Pennsylvania and some of the adjacent states, is more remarkable for endurance than symmetry. In height it sometimes reaches 17 hands, the legs being long and the carcass light. The Conestoga breed make good carriage and heavy-draught horses.

Virginia and Kentucky horse. This breed, which predominates in the states named, and, to a greater or less extent, in all the Southern, Middle, and Western States, derives its origin from English blood horses imported at various times. It has been most diligently and purely preserved in the South. The celebrated Shark, the best horse of his day, was the sire of the best Virginia horses, whilst Tally-ho, a son of Highflyer, peopled the Jerseys. (Farmer's Register, vol. ii.)

In the Southwestern States, wild horses abound, which are doubtless sprung from the same Spanish stock as the wild horses of the Pampas and other parts of the Southern continent, all of which are of the celebrated Andalusia breed, derived from the Moorish Barb.

The prairie horses are often captured, and, when domesticated, are found to be capable of great endurance. They are not, however, recommended by the symmetry or elegance of appearance, for which their type is so greatly distinguished, being generally rather small and scruffy.

The following interesting observations relative to some of the American breeds, were lately addressed by the editor of the New York Spirit of the Times to the editor of the Cultivator.

Fifteen years ago, thousands of dollars would have been wagered, that no horse in the world could trot a mile within three minutes; as many would be laid down now, that it could be done in two minutes twenty-eight seconds. Ten years ago, to drive a horse 70 miles between sun and sun, would have been deemed a great performance; but since strains of the blood of old Messenger have been introduced into our road stock, at the North, hundreds of horses can be found that can travel from 80 to 90 miles without distress. In our paper of this day is a report of the performance of a horse in Boston that, without being trained, was driven 103 miles between sunrise and sunset, over a hilly road, before a carriage, which, with the rider, weighed 470 lbs.

The acknowledged superiority of northern carriage and draught stock is owing almost entirely to the fact, that thorough-bred horses have found their way north and east from Long Island and New Jersey, where great numbers are annually disposed of that are unsuited to the course. The use of thorough and half-bred horses, for domestic purposes, is becoming so common in England, that in a few years, no other will be used for the road. The half-bred horse is not only much handsomer, but his speed and powers of endurance are infinitely greater. His head and neck are light and graceful, his limbs fine, his coat glossy and soft as satin, while his action is spirited, and his courage and stamina sufficient to carry him through a long journey without his falling off in condition, or to undergo an extraordinary trial of speed and game without distress. The ordinary cocktail is, in most instances, a mere brute, that in travelling, sinks daily in strength, losing his appetite, and, of course, his flesh and action, so that at the termination of a ten days' journey, he is nearly knocked up; he can travel but about 40 miles per day, and requires the whole day to perform this distance. An eminent southern turfman, well known the country over, recovers his horses on a journey; they are all from the North, and have a dash of blood in their veins; after driving them hard about his plantation in the spring, until they begin to look thin and rough, he starts on his annual journey, and by the time he reaches the Virginia Springs, his horses are literally as fine as silk, with fine coats, great spirit, and in good condition for fast work. In travelling, he starts early, and drives at the rate of 8 or 9 miles the hour until 10 o'clock, when his horses are taken out, rubbed dry, watered, and fed. In the cool of the day, they are again harnessed, as fresh as if they had not travelled a mile. In this way he accomplishes a long journey, travelling between 50 and 60 miles a day, without fatigue.
HORSE.

...to himself or injury to his horses. The slow-going, no-giving sort of style in which horses are jogged along at a small's pace all day under a hot sun, knocks them up in a short time; they would neither tire nor lose flesh in double the time, if driven sharply a few hours in the morning and evening, allowing them to rest in the middle of the day. It is the all-day work that knocks up horses, not the pace.

Our friends of the *Cultivator* may not be aware of the vast amount invested in thorough-bred horses at this moment in the United States, or of the prices some of fashionable blood command. We may state, from research and information communicated by Mr. Harris to the *Cabinet* for April, 1842, and furnish much information that must be esteemed valuable:

"Diligence is of a handsome dapple-gray colour, measures 15 hands, and is one of the most perfect animals of the distinguished breed of Normandy horses called *Percheron*. He was chosen as a full-sized specimen of the breed, possessing all the quick action of the smaller horses, in order that his immediate progeny from our light mares might approach nearer the true type of the race. It must be observed, however, that it is more in breadth and size of bone and muscle that he exceeds the standard, than in his height, which is very little above the average. An inspection of the horse will convince any one that this race is the origin of the Canadian pony, about whose valuable properties little need be said, as they are well known and highly prized in this section of the country, and still more to the North, where they have, undoubtedly, given that stamina and character to the horses of Vermont, New Hampshire, and the northern section of New York, which makes them so highly valued all over the Union as road horses; while it is a remarkable fact, that in those states where the attention of breeders has been exclusively devoted to the English race-horse, the carriage and the stage-horse is almost universally supplied from the North. It remains, therefore, for breeders to determine whether it is not better to resort to the full-sized Percheron to cross upon our light and already too highly-bred mares, than to use the degenerate in size only, through the rigour of the climate, for it must be admitted that the little animal retains all the spirit and nerve of his ancestors, and lacks strength only in proportion to his size. My own opinion is, that a due portion of the French blood mixed with the English will produce a stock of horses invaluable, as combining all the properties that are required for quick draught on the road or the farm. I need not assure you, who are acquainted with the success of Diligence as a stud-horse in this place, that such too is the opinion of the farmers of New Jersey.

"I have frequently been questioned as to my reasons for selecting this horse for farmers' use in preference to the English draught-horse. My reply has always been, that the draught-horse of England, whenever brought to this country, must prove a failure; he wants the go-ahead principle; he cannot move out of a walk, which is saying quite enough for him, without dwelling upon his defects of form, which can only be concealed by loads of fat,
and not even then, from the eye of the horseman. The true Percheron, or Norman Dili-
gence horse, on the contrary, combines more strength with activity than any horse I have
ever sat behind. All travellers, on entering France, are struck with the properties of these
horses, as displayed in drawing the ponderous mail-coaches called a Diligence, by which they are
conveyed through the kingdom at the rate fully equal to the average of stage travelling in this
country. English horsemen confess that their road-horses could not hold out the same pace
before the same load.

"The origin of this race, according to French authorities, dates from the occupation of the
Netherlands by the Spaniards, who introduced the Andalusian horse, which soon became the
favourite stud-horse all over the continent. The Spanish horse is known to spring from the
Barb or Arabian, introduced by the Moors on their conquest of that country. All who are
conversant with the history of the horse, know that the Andalusian has always been cele-
brated for his beauty, and for his great spirit, combined with extraordinary powers of endur-
ance. The French horse, upon which he was crossed, was the old Norman draught-horse,
which still exists in the country in all its purity, and is perhaps the best of all horses for
slow draught.

"The average height of these horses is 16
hands, and they may be described as follows: Head short, wide, and hollow between the eyes;
jaws heavy; ears small, and pointed well for-
wards; neck very short and thick; mane heavy;
shoulder well inclined backwards; back extremely short; rump steep; quarters very broad;
chest deep and wide; legs very short, particularly from the knee and hock to the fetlock, and
thence to the coronet, which is covered with long hair, hiding half the hoof; much hair on the legs; tendons large, and
muscles excessively developed."

An English writer in the British Quarterly
Journal of Agriculture, thus speaks of the Nor-
man horse. After giving an account of its
origin, which he agrees in tracing to the Spa-
nish horse, he observes, "The horses of Nor-
mandy are a capital race for hard work and
scanty fare. I have never seen such horses at
the collar, under the diligence, the post-car-
rriage, the cumbersome and heavy voitures or ca-
biots for one or two horses, or the farm cart.
They are enduring and energetic beyond de-
scription; with their necks cut to the bone,
they clinch not; they put forth all their efforts at
the voice of the brutal driver, or at the dreaded sound of his never-ceasing whip; they
keep their condition when other horses would
die of neglect and hard treatment. A better
cross for some of our horses cannot be ima-
gined than those of Normandy."

Whilst lately in Europe, Professor Gibson,
of Philadelphia, a passionate admirer of the
horse, and well versed in the finest blood of
the United States, made close observations of
the horses in different parts of England and
Ireland. The following passage from his
"Rambles" furnishes a condensed view of the
results of his observations:

"The Irish horses have long been consider-
ed the finest in the kingdom, and certainly
I saw none to be compared to them in any
part of Europe. In general they are very
compact, strong, active, and spirited, but high-
tempered, and difficult to manage. They bear
a close resemblance to our Vermont horse in
style, action, and shape, and might readily pass
for the same breed, with the exception of being
larger. In England they bring high prices,
and it is not uncommon to meet with English
dealers at the Irish fairs buying them up, in
great numbers, for their own markets. The
English horse, indeed, within the last 20 years,
had degenerated so much, in some respects, as
to not to serve the many useful purposes to which
he was accustomed at that period, owing to
breeders having run too much upon blood.
On this account it is now hardly possible to
meet with any of the old stock of hunters
so large and powerful, and with so much
bone and sinew; so that even in York-
shire I saw but a single specimen, a fine
black, in possession of Mr. Whittaker, of O-
ley, 30 years of age, but which felt under me
like a colt, after a ride of 20 miles. Even
the carriage horses, indeed, throughout every part
of England, are conspicuous for their long,
low necks, slab sides, and spindle shanks, and
very inferior, as a race, to our own stock, for
the same purposes. In London, it is true, large
showy animals are to be seen in the car-
riages of noblemen and other persons of
fortune; but they are procured at immense
prices, often 400 or 500 pounds each, and
even then are deficient in action, and too often
have broken knees, to which indeed most of
the English horses are so liable, as seldom to
be led or ridden out by the groom without
having their knees protected by leather or
woollen covers or caps. The Irish horse, on
the contrary, is not apparently so high bred as
the English, and therefore a better animal for
draught, saddle, and most other purposes. Yet
no blood horses in England have proved super-
ior to the Irish racer in speed, bottom, and other
requisites; and I believe it is admitted on all
hands that there is now no horse in the British
empire to be compared to Irish 'Harkaway,'
bred and owned by a linen-bleacher of Belfast.
A great many inquiries were made of me,
also, respecting 'Skylark,' an Irish horse im-
ported into this country a few years back, and
represented, by all that spoke of him, as a
most extraordinary animal, and one that never
should have been allowed to leave the king-
dom. Both animals I had an opportunity of
seeing—the one in England, and the other in
Richmond, Virginia, soon after his arrival—
and finer specimens of the kind I cannot ima-
gine to exist in any country. Through every part
of Ireland I travelled, I could not help being
struck with the form and activity of all classes
of horses; and in Dublin, especially, scarcely
passed a day without noticing ladies and gen-
tlemen splendidly mounted, the finest teams in
mail and county coaches, and extraordinary
numbers of beautiful and well-proportioned
animals, which, however, command there as many pounds sterling as American horses—excepting,
perhaps, first-rate trotters—dollars in this coun-
try; and it is only surprising some of our
613
HORSE, AGED OF. See Ages of Animals.

HORSE-CHESTNUT. If, says a writer in the American Farmer (vol. xiv.), the value of this nut was more generally understood, it would not be suffered to rot and perish without being turned to any account, as at present. The horse-chestnut contains a saponaceous juice, very useful, not only in bleeding, but in washing linens and other stuffs. The nuts must be peeled and ground, and the meal of them is sufficient for 10 quarts of water; and either linens or woollens may be washed with the infusion, without any other soap, as it effectually takes out spots of all kinds. The clothes should, however, be afterwards rinsed in spring water. The same meal, steeped in hot water and mixed with an equal quantity of bran, makes a nutritious food for pigs and poultry. See Chestnut, Horse.

HORSE DEALERS. Persons whose business it is to buy and sell horses. Each person carrying on the business of a horse dealer is required to keep a book, in which he shall enter an account of the number of horses kept by him for sale and for use, specifying the duties to which the same are respectively liable. This book is to be open at all reasonable times to the inspection of the officers; and a true copy of the same is to be delivered quarterly to the assessor of the parish in which he resides. Penalty for non-compliance, 50l. (43 Geo. 3, c. 161.) Horse dealers are assessed if they carry on their business in the metropolis 25l., and if elsewhere, 12l. 10s. per annum. From the papers published by the Board of Trade, it appears that the number of persons of this class assessed in 1831, was 74 in the metropolis, and 903 in other parts of the kingdom.

HORSE, DISEASES OF. See each disorder.

HORSE-FLY or FOREST-FLY (Hippobosca equina, Linn.). In England this fly lives chiefly on horses, but sometimes also attacks horned cattle and other mammals. The male is scarcely so large as the house-fly; the female is larger. The insect generally attaches itself to the abdomen of the animal, which is least covered with hair, particularly between the hind legs. This fly has a singular movement: it runs very quickly, but sideways like a crab: it is covered with a hard crust; and adheres so firmly by its claws as to render it difficult to take off. As it torment the animals very much, means of driving it away must be thought of. Picking off by hand is too troublesome. By the following remedy it may be got rid of in 24 hours' time: take of mineral earth eight ounces; hard one pound, and make them into a salve. Some of this salve is to be rubbed on here and there upon the hair, and worked in with a wisp of straw. After 24 hours the salve is to be washed off with warm water, in which brown soap has been dissolved. Care must be taken for some days that the horse does not catch cold. (Kollar on Insects, Miss Loudon's Trans.) See Gan-Fry.

HORSE-HOE. THE. For this valuable implement of agriculture, the farmer is indebted to the justly celebrated Jethro Tull. Previous to his time, we search in vain in the works of agricultural authors for the slightest allusion to such an instrument. The production of the horse-hoe, indeed, seems to have been almost a natural consequence of the adoption of the drill system, for which also the cultivator is mainly indebted to Tull. He gave in his Husbandry, more than a century since, an engraving of a horse-hoe of his own invention, which resembles a common, rudely-shaped swing plough, with the mould board omitted, and the shares having a cutting edge turned up on its landside. A variety of improvements were gradually made in the construction of this implement, and it is now considered to be the best.

The advantages which these possess over the hand-hoe are very fairly stated by the late Mr. Francis Blakie: he remarks, "In many cases the hand-hoe may be used to advantage, and should then be so used. But generally speaking, the hand is not so efficient as the horse-hoe. Expediency is a most material point in all processes of husbandry, carried on in a variable and uncertain climate, and it frequently happens that hoeing, in any way, can only be executed to advantage, in a very few days in spring: hence the horse-hoe has a most decided advantage over the hand-hoe, for a man will only hoe about half an acre a day with the latter, while, with the former, a man and a boy, with one horse, will hoe eight or ten acres a day, and that in a more effectual manner." (On Farm-yard Manners, p. 39.)

Among the most approved implements of the kind in England, are the following:

Clarke's Universal Ridge Horse-hoe.—This is a very ingenious contrivance for carrying out the several operations of ridge culture. It is adapted for the uses of a double tom, a moulding plough, a broad share or cleaning plough, and a horse-hoe. It is only as fitted for the latter purpose that we have now to describe it: its other forms will be given under the head Plough.

To the frame of the plough is attached a pointed share, which serves as a hoe for the centre of the furrow: a movable frame is attached to the beam, which is readily adjusted to any given width: to this is attached, when it is intended to hoe plants upon the ridge, the stalks of two curved hoes; when used upon flat work, the flat hoe should be substituted for the curved or inverted hoe. This forms a very perfect and simple horse-hoe.

Blakie's Inverted Horse-hoe.—This excellent hoe, which was the first that successfully hoed between several rows of turnips at once, and which led the way to the recent improvements of Mr. Garrett, was intended to be attached to a drill-carriage, or any light axletree, by the draft-irons fixed to the handles. Blakie described it pretty accurately when he said, "It is adapted for cleaning between rows of plants, growing at narrow intervals, within which it may be worked with perfect safety when in their infant state; indeed the idea first struck me on observing a large proportion of the plants buried by the operation of the hoes formerly in use."
HORSE-HOE.

Garrett's Horse-hoe.—This horse-hoe, invented by the manufacturers, Garrett and Son, of Leiston, Suffolk, is suited to all methods of drill cultivation, whether broad, stetch, or ridge ploughing; and is adapted to hoeing corn of all kinds as well as roots. The peculiar advantage of the implement act that the width of the hoes may be increased or diminished to suit all lands, or methods of planting: the axletree being movable at both ends, either wheel may be expanded or contracted, so as always to be kept between the rows of plants.

The shafts are readily altered, and put to any part of the frame, so that the horses may either walk in the furrow, or in any direction, to avoid injury to the crop.

Each hoe, or each pair of hoes, works on a lever independent of the others; so that no part of the surface to be cut, however uneven, can escape; and in order to accommodate this implement to the consolidated earth of the wheat crop, and also the more loosened top of spring corn, roots, &c., the hoes are pressed in by different weights being hung upon the ends of each lever, and adjusted by keys or chains, to prevent their going beyond the proper depth.

And what has hitherto been an objection to the general use of the horse-hoe is avoided in this, by adopting a mode of readily shifting the hoes, by a plan similar to that of the steergear, so that the hoes may be guided to the greatest nicety. This implement is so constructed that the hoes may be set to a varying width, from seven inches to any wider space; the inverted hoes are preferred when the distance between the rows is sufficient to admit two of them; or any other form that may be considered best for the purpose.

Lord Ducie's Expanding Horse-hoe.—The parallel expanding horse-hoe is used for hoeing drill crops, and is constructed principally of wrought iron: it has five tines, and can be regulated to any width, from 12 to 27 inches, with the greatest facility, so that the time shall always present its edge to what it has to cut: this is effected by the support of each tine moving parallel with the beam: it is worked on the principle of the parallel rule; the machine has one wheel in front, with a tiller for the horse to yoke to: the depth it enters into the ground is regulated by raising or lowering the wheel; there is a pair of handles for the man who attends the machine to steady it by.

Grant's Horse-hoe, and Moulding Plough. By substituting mould-boards in the place of the wrought iron frame and hoes, this horse-hoe becomes a moulding plough.

White's Double-action Turnip Hoe.—This implement is constructed so that it may be used with only one horse and a man, and is intended to hoe either broadcast, drilled, or ridged turnips. It hoes two rows lengthways and crossways at one time when necessary. It can be set to suit the drills at any distance, from 15 to 30 inches, and to leave the distance of each turnip 9, 12, or 15 inches apart: it may be used also as a scarifier by removing the cross-cut hoes, and replacing them with spear-footed tines. (See Cultivator.)

HORSE-RADISH.

HORSE-RADISH. (Coelchearia Armoracia). A species of wild mint, growing freely in waste ground, especially in watery places. It is a perennial, blowing dense crowded whorls of small, pale purple flowers in August and September in England. The whole herb is of a hoary or greyish green, clothed with fine soft downy hairs, and exhaling a strong peculiar scent. The stems are 2 or 3 feet high, rather bluntly quadrangular; the leaves nearly sessile, 1½ to 2½ inches long, spreading, strongly and sharpish serrated, acute; their upper surface hoary; under, shaggy, with dense soft white hairs. It affords oil by distillation with water. The infusion of it allays sickness.

The plant commonly called Horse Mint, in the United States, is the monarda fistulosa of botanists—sometimes called Wild Bergamot. It has a perennial root, and stems 2 or 3 feet high, branched, mostly hairy, especially at the joints and towards the summits. The violet-purplish or often greenish-white or flesh-coloured flowers are pubescent or downy. This, says Dr. Darlington, is a variable plant; and Mr. Bentham has reduced several species of preceding authors into this one. Five or six additional species of Monarda are enumerated in the United States. (Flora Cestrica.)

HORSE POWER, in steam-engines, is estimated by Mr. Watt at 32,000 pounds avoidably lifted six foot high per minute for one horse. M. D'Aubuisson, from an examination of the work done by horses in the whims or gigs (machines à mulettes) for raising ore from the mines at Freyberg, the horses being of average size and strength, has concluded that the usual effect of a horse yoked during eight hours, by two relays of four hours each, in a manège or mill course, may be estimated at 40 kilogrammes raised 1 metre per second, which is nearly 16,440 pounds raised one foot per minute; being very nearly one-half of Mr. Watt's liberal estimate for the work of his steam-engines.

HORSE-MINT (Mentha sylvestris). A species of wild mint, growing freely in waste
vegetate at all. Mr. J. Knight recommends, for the obtaining a supply of the crowns, any inferior piece of ground to be planted with sets, 6 inches apart and 6 deep; these will furnish from 1 to 5 tops each, and they may be collected for several successive years with little more trouble than keeping them clear of weeds.

Horse-radish may be planted from the close of January until the same period in March, but the best times are in October and February; the first for dry soils, the latter season for moist ones.

The sets must be inserted in rows 18 inches apart each way. The ground should be trench ed between 2 and 3 feet deep, the cuttings being placed along the bottom of the trench, and the mould turned from the next one over them, or inserted to a similar depth by a long, blunted dibble. When the planting is completed, the surface should be raked level, and kept clear of weeds, until the plants are of such size as to render it unnecessary. It is of great benefit if the mould lies as light as possible over the sets; therefore, treading on the beds should be carefully avoided. They speedily take root, and send up long straight shoots, which make their appearance in May or June. The only cultivation required is to keep them free of weeds, and as the leaves decay in autumn, to have them carefully removed; the ground being also hoed and raked over at the same season, which may be repeated in the following spring before they begin to vegetate. In the succeeding autumn they merely require to be hoed as before, and may be taken up as wanted. By having three beds devoted to this root, one will always be lying fallow and improving, of which period likewise advantage should be taken to apply any requisite manure. If the plants, when of advanced growth, throw out suckers, these should be carefully removed during the summer as they appear. In September or October of the second year, the roots may be taken up, and in November a sufficient quantity should be raised to preserve in sand for winter supply. To take them up, a trench is dug along the outside row, down to the bottom of the upright roots, which by some persons, when the bed is continued in one place, are cut off level to the original stool, and the earth from the next row is then turned over them to the requisite depth, and so in rotation to the end of the plantation. By this mode of bed will continue in perfection for 3 or 6 years, after which a fresh planta tion is usually necessary. But the best prac tice is to take the crop up entirely, and to form a plantation annually, for it not only causes the roots to be finer, but also affords the opportunity of changing the site. If this mode is followed, care must be taken to raise every lateral root, for the smallest of them will vegetate if left in the ground. See Scurvy-Grass.

HORSETAIL (Equisetum, from eques, a horse, and seta, hair, in allusion to the fine hair like branches). Although the plants of this genus are looked upon as mere weeds, they have a very interesting aspect when seen growing in their natural situations; they are found in boggy places, and multiplied by di visions. Several of the species, like grasses, secrete a quantity of limy earth (silica) mostly lodged in their articulations. There are seven indigenous species.

1. Branched wood horsetail (E. sylvaticum), growing in shady moist woods, by trickling rills, but not very frequent. This is a very elegant species, 12 or 18 inches high; stems erect, beset with many whorls of slender, compound, angular, smooth, spreading branches.

2. Great water horsetail (E. fluviatile). Horses eat this plant with avidity, and in some parts of Sweden it is collected for the purpose of serving them as winter food; flourishing in watery places, about the banks of rivers and lakes. This is by far the largest English spe cies, differing from the foregoing in the fructification, which is a large cylindrical catkin, having four or five pale teeth on a separate short stem, differing from the branched or whorled frond, as is likewise the case with the following one, E. arvense: all the others hitherto observed in Britain have terminal catkins at the top of the fronds. The terminal stems of the great water horsetail are quite erect; at least a yard high, often much more, furnished from top to bottom with whorls of numerous long slender branches. The catkins are brown, with scales, which separate and show the white scales when they are ripe.

3. Corn horsetail (E. arvense). This, in England, is a very common species growing in wet meadows and moist grain fields. It is a most troublesome weed in pastures, and is seldom touched by cows, unless pressed by hunger, when it occasions an incurable diarrhoea; it is eaten with impunity by horses, but is noxious to sheep. The fronds are reckoned unwholesome to such animals as feed upon them in autumn, especially swine. This rough grass is employed for cleansing and polishing tin vessels. In this species the root is much branched, creeping extensively, producing in the spring several simple, upright, flowering stems quite destitute of branches; a span high, cylindrical, smooth, juicy, of a pale brown, bearing three or four brown-ribbed sheaths, and at the top a solitary catkin.

4. Marsh horsetail, or paddock pipe (E. palustre). This species grows most frequent in spongy watery bogs, and other marshy places, flowering in June and July. The stem is rather slender, deeply furrowed, beset throughout with whorls of slender, angular, minutely rough branches.

It is not so strong as the preceding species, but is equally prejudicial to cows. It is also very troublesome in drains, within which it vegetates, and forms both stems and roots several yards in length: thus the course of the water is interrupted, and the drains are totally obstructed.

5. The smooth naked horsetail (E. limbosum) grows also in marshy watery places, and has stems stouter than the last, about two feet high, very smooth to the touch, though finely striated.

6. Greater rough horsetail. Shave-grass pewterwort (E. hyemale). This species is found in boggy woods, but not very common. The root is black, variously branched; stems
of a deep glaucous green, from one to two feet high, cylindrical, uniformly and rather copiously furrowed, the furrows minutely toothed and of a strong hardness. This species is wholesome to horses, and is eaten by them; but it is hurtful to cows and disagreeable to sheep. That eminent chemist, Sir H. Davy, first detected a quantity of pure silex in the furrowed cuticle of this plant, which accounts for its power, as a file, in polishing wood, ivory, or even brass. This purpose it has long served in England, under the name of Dutch rushes, being usually imported from Holland, and is chiefly employed by turners and cabinetmakers to polish their work, as well as by dairy-maids for cleaning horns and other utensils. So wheel-straw, whose cuticle contains the same earth in an impalpable state, like others of the natural family of grasses, is used, when burnt, to give the last polish to marble.

Mr. Nuttall observes that this species is very abundant on the banks of the Missouri below the Platte, and called "Rushes." It is, he says, found to be injurious to horses which feed upon it for any considerable length of time. (Eng. Flor. iv. 335—"in the Williams Encyc.")

**HORTICULTURE** (Lat. hortus, a garden, and colo, I cultivate). The culture of the kitchen garden and orchard. The chief difference between horticulture and agriculture is, that in the former art the culture is performed by manual labour in a comparatively limited space, called a garden; while in the latter it is performed jointly by human and animal labour in fields, or in an extensive tract of ground called a farm.

**HOVEN.** A genus of herbaceous plants, of which only two species grow wild in Great Britain. The cultivated foreign species are pretty border plants, succeeding in any common soil, and readily multiplied by division.

1. Common hound’s-tongue (C. officinale) is found abundant in waste ground and by road-sides. The root is fleshy and tapering. The whole herb of a dull green, downy, and very soft, exhaling when touched a pungent and nauseous odour. When bruised it is affirmed to drive away mice. The stem grows to two feet high, branched, leafy, furrowed, and hairy, bearing terminal paniced clusters of dull crimson flowers. This plant is eaten by goats, but refused by sheep, horses, hogs, and cows. It has a bitter taste, and is esteemed powerfully narcotic and dangerous for internal use. The roots are astringent and sedative; and are used externally and internally in decoction in cases of scrofula.

2. Green-leaved hound’s-tongue (C. sylvaticum). This is a more rare plant, growing by road-sides and hedges in shady situations, and is distinguished from the common species in its bright shining green colour, and want of downy softness, besides having scarcely any scent. The flowers, which blow in June, are at their first opening reddish, subsequently of a dull blue. (Smith’s Eng. Flor. vol. i. p. 259; Paxton’s Bot. Dict.)

Four species of this plant are enumerated in the United States. The common hound’s-tongue is a foreigner, now frequent in the Middle States, and extending itself throughout the country. It is a biennial, and may be readily known by its disagreeable odour, somewhat resembling that of young mice. It formerly enjoyed some reputation for medicinal properties.

The wild comfrey (C. Virginicum) has a perennial root, and is common in rich woodlands. The root is mucilaginous, and frequently employed, in domestic practice, for complaints of the chest, internally, and externally in poultices for bruises, sprains, &c.

**HOUSELEEK** (Sempervivum, from semper, always, to live forever; the tenacity of life in the houseleek is well known). There are seven species of houseleek mentioned by Miller (but these are only a few of this extensive genus). They all thrive best on dry rocky situations. These interesting plants are worthy a place in every collection. The mountain houseleek is a very hardy perennial, bearing a purple flower in June and July. The houseleek (S. arboresum), which is a native of the Levant, is hardy and handsome, bearing a golden-yellow flower in autumn and even in winter. Cuttings taken off and laid to dry for two or three days, will root very freely. The juice of the common houseleek (S. tectorum), applied either by itself or mixed with cream, gives immediate relief in burns or other external inflammations. (Paxton’s Bot. Dict.)

**HOVEN.** See CATTLE, and SHEEP, Diseases of.
HUMUS.

HUMUS.

HUMULLEL, BARLEY. An instrument for separating the awns of the barley plant from the seed. There are various modes of taking off the awns: a common one is by treading it by a horse walking over it; another, by rolling it with a grated roller, an instrument something similar to a garden roller, the cylin-
der being formed of thin, flat, wrought iron bars, placed about two inches apart, and the edges to the surface: this, rolled over the barley, takes off the awns or ailes. We have also seen a grated presser or hopper, about a foot square, barred across with the plates, which is literally knocked down by the workman, and thus chops off the awns. But the best machine we have seen is one upon a wood stand, with a hopper into which the barley is thrown, from whence it falls into a box in which a spindle is placed in an inclined position, having, when at a few inches apart, short knives placed spirally, so as to form a sort of screw, which, when put in motion, has a tendency to draw the barley from the upper end of the box to the lower: during the separation the awns of the barley are effectually knocked off. This mode of dressing barley constitutes one of the principal improve-
ments in Salter's patent winnowing machine, which will be described hereafter; but the hummeller is made in the form described for barley only, by several makers. See WINNOW-
ING MACHINE.

HUMUS. A modern term given by some chemists to the very finely divided organic matter which all cultivated soils contain, and which is generally regarded as the chief element of fertility, the source from which plants are directly nourished. Woody and vegetable fibre in a state of decay constitutes the sub-
stance called humus. Liebig lays it down as established, that man and other animals derive the means of their growth and support from the vegetable kingdom, whereas plants find new nutritive material only in inorganic sub-
stances. According to this doctrine, humus, being the product of organic matter, does not contribute direct nourishment to plants, but only constitutes a medium and agent through which their nutriment is derived. "The opi-
nion," he observes, "that the substance called humus is extracted from the soil by the roots of plants, and that the carbon entering into its composition serves in some form or other to nourish their tissues, is so general and so firmly established, that hitherto any new argu-
ment in its favour has been considered unnee-
cessary; the obvious difference in the growth of plants, according to the known abundance or scarcity of humus in the soil, seemed to afford incontestable proof of its correctness."

"Yet this position, when submitted to a strict examination, is found to be untenable; and it becomes evident from most conclusive proofs that humus, in the form in which it exists in the soil, does not yield the smallest nourishment to plants.

"The adherence to the above incorrect opinion has hitherto rendered it impossible for the true theory of the nutritive process in vegeta-
bles to become known, and has thus deprived us of our best guide to a rational practice in agriculture. Any great improvement in that most important of all arts is inconceivable without a deeper and more perfect acquaint-
ance with the substances which nourish plants, and with the sources whence they are derived; and no other cause can be discovered to ac-
count for the fluctuating and uncertain state of our knowledge on this subject up to the present time, than that modern physiology has not kept pace with the rapid progress of chemistry."

The chemical process through which humus is usually obtained, is by making an alkaline solution or decoction of mould, peat, soot, woody fibre, &c., and adding to such decoction acids. The flocculent matter precipitated is called humic acid, a substance but slightly solu-
able in water, requiring no less than 2500 times its weight for this purpose. The comp-
ounds which it forms with alkalies, lime, and magnesia, have the same degree of solubility. (Sprengel.)

"Vegetable physiologists agree in the suppo-
sition that by the aid of water humus is rendered capable of being absorbed by the roots of plants; but, according to the observation of chemists, humic acid is soluble only when newly precipitated, and becomes completely insoluble when dried in the air, or when ex-
posed in the moist state to the freezing tempera-
ture. (Sprengel.)

"Both the cold of winter and the heat of summer, therefore, are destructive of the solu-
bility of humic acid, and at the same time of its capability of being assimilated by plants; so that, if it is absorbed by plants, it must be in some altered form.

"According to Dr. Jackson, the substances con-
tained in humic extract form soluble salts with lime. The acids form soluble salts with the same substance, and the salts are decom-
pared in the process of vegetation.

"The correctness of these observations is easily demonstrated by treating a portion of good mould with cold water. The fluid remains colourless, and is found to have dissolved less than 100,000th part of its weight of organic matter, and to contain merely the salts which are present in rain-water.

"Decayed oak wood, likewise, of which hu-
ic acid is the principal constituent, was found by Berzelius to yield to cold water only slight traces of soluble materials; and I have myself verified this observation on the decayed wood of beech and fir.

"These facts, which show that humic acid in its unaltered condition cannot serve for the nourishment of plants, have not escaped the notice of physiologists; and hence they have assumed that the lime or the different alkalies found in the ashes of vegetables render soluble the humic acid, and fit it for the process of as-
similation.

"Alkalies and alkaline earths do exist in the different kinds of soil in sufficient quantity to form such soluble compounds with the humic acid.

"Other considerations, of a higher nature, con-
fine the common view respecting the nutri-
tive office of humic acid, in a manner so clear and conclusive, that it is difficult to conceive how it could have been so generally adopted.

"Fertile land produces carbon in the form
HURDLE.

The name of a disease in sheep which speaks for itself. It is occasioned by poor living, especially during the winter, and is best cured by better keep.

HURDLE (from the Sax. hyrne, to keep, or the Germ. horden). The hurdles of the ancients (crates) were somewhat similar to those of the moderns; they were a kind of wicker-work, and used for various purposes. When employed for drying figs or grapes, they were called ficaria: they were also used for screening fruit from the weather. (Colun. xii. 15.) Hurdles, Virgil informs us (Georg. i. 94), were employed as harrows to level the ground which had been turned up by the rastrum, or heavy rake. They are also employed to feed silk-worms upon. In modern husbandry, hurdle implies a light frame of wood or iron, somewhat in the form of the common gate, constructed for the purpose of forming a movable fence for the confining of sheep and other animals. They are generally made of some light split timber, or of hazel-rods wattle together. These are principally employed where sheep are folded on arable lands, or where they are fed with turnips in the field, to keep them on a certain space of ground, or to confine them to a certain portion of their food at a time, in which way they are extremely useful; as the sheep, by being so closely confined, contribute greatly to the improvement of the land, in the first case; and they improve by having a given quantity of food allowed them at once, with less loss than they would do if allowed to range at large over the field.

A dozen and a half hurdles will hold thirty sheep, and twelve dozen, one thousand. On the South Downs the allowance is three sheep to a hurdle: this of course varies with the description of sheep. A shepherd and his dog, without any other assistance than having the hurdles carted to the field, will, with the requisite number of hurdles, feed off one hundred acres of turnips. “The number of hurdles required (Quart. Journ. of Agr. vol. iii. p. 647), is one row the whole length of the ridges of an enclosed field, and as many more as will reach twice across two eight-step lands or ridges, or four four-step lands. This number is sufficient for a whole quadrangular field, whatever number of acres it may contain. The daily portions are given, more or less, according to the number of the flock. Two of these portions are first set off, or “pitched,” the sheep being let in on the first or corner piece. Next day they are turned into the second piece, and the cross-hurdles that enclosed them in the first are carried forwards and set to form the third piece. These removements are continued thus till the bottom of the field is reached: both the cross-rows are then to spare, and are carried and set to begin a new long row, close to the off-side of a furrow, and the daily folding carried back over two or four lands, as at first. It is always proper to begin at the top of the field, if there be any difference in the level, in order that the

HUNDRED.

of wood, hay, grain, and other kinds of growth, the masses of which differ in a remarkable degree.” (Liebig.)

In relation to the fact observed of carbon and humus often becoming every year more abundant, in spite of cropping, Mr. Ruffin, an author so advantageously known to the American agriculturists from the views of Liebig is in admitting that land receives no manure, even when none is conveyed to it by man. In the case of cultivated lands, from which crops are taken off, the quantity, it is true, is small, compared with that of a forest, where much is left to fall and rot. Mr. Ruffin maintains, that so much carbon is derived from the atmosphere, through the leaves of growing plants, that more than half the whole products may be taken away, and the other half may supply as much humus and carbon, or, perhaps, even cause an increase of both. The severely cropped lands of the United States, Mr. Ruffin considers as affording many examples of the draught upon the land being carried beyond the amount supplied, and a proportional reduction in the quantity of humus. See Green Manures.

“The humic acid of chemists,” observes Liebig, “is a product of the decomposition of humus by alkalies: it does not exist in the humus of vegetable physiologists.” He says in another place, “Transformations of existing compounds are constantly taking place during the whole life of a plant, in consequence of which, and as the result of these transformations, there are produced gaseous matters which are excreted by the leaves and blossoms, solid excrements deposited in the bark, and fluid soluble substances, which are eliminated by the roots. Such secretions are most abundant immediately before the formation and during the continuance of the blossoms: they diminish after the development of the fruit. Substances containing a large proportion of carbon are excreted by the roots and absorbed by the soil. The soluble matter thus acquired by the soil is still capable of decay and putrefaction; and by undergoing these processes furnishes renewed sources of nutrition to another generation of plants, and it becomes humus. The leaves of trees which fall in the forest in autumn, and the old roots of grass in the meadow, are likewise converted into humus by the same influence: a soil receives more carbon in this form than its decaying humus had lost as carbonic acid. Humus does not nourish plants by being taken up and assimilated in its unaltered state, but by presenting a slow and lasting source of carbonic acid, which is absorbed by the roots, and is the principal nutriment of young plants at a time when, being destitute of leaves, they are unable to extract food from the atmosphere.” (Liebig’s Organic Chemistry.)

Some recent experiments of Saussure go to prove that plants do assimilate humus as direct nourishment, contrary to the views of J. L. Gay-Lussac. These experiments are carried on by feeding the plants, who, as we have seen, regards it only as a medium by which nourishment is absorbed and subsequently given out.

HUNDRED. An ancient division of a country, which originated either from its being occupied by 100 families, or because every such district found the king 100 able-bodied men for his wars. They were first constituted by Alfred the Great. He is supposed to have derived the idea from northern Germany; but there centa, or centena, is a jurisdiction over 100 towns.

HUNDRED-WEIGHT. A weight of 112 lbs. avoirdupois, generally written cwt.

51
649
flock may have the driest lair to retire to in wet weather. In the setting of hurdles, an iron crowbar, or fold pitcher, is employed, by which much time and loss by breakage of the hurdles is effected." New hurdles, in the south of England, are about 16s. per dozen. They are made at 4d. by professed hurdle-makers, who find their own tools; they make about a dozen per day. A larger kind of hurdles, called park hurdles, cost 2s. each, and iron hurdles about 4s. 6d. to 6s.; and these are, in the long run, for permanent divisions, more economical than wooden ones. A new kind of iron hurdle for feeding sheep in gardens and pleasure-grounds is described, with a wood engraving, by Mr. Baist (Ibid. vol. ii. p. 113), and the complete process of wooden hurdle-making is given, Ibid. vol. iii. p. 647. There is also another kind of hurdle, made with twisted hazel-rods, very common in the south of England, whose first cost is less than the other kinds, but they do not last so long, and sooner get out of repair.

The farmer who uses the ash hurdles would find the adage, on the sound of durability, of charring (old plastering) that portion of them which goes into the ground. Net hurdles are also sometimes economically used; but they are rather more troublesome than wooden or iron hurdles, and require to be kept carefully in a dry place, when not in use. There is a very elaborate paper on hurdling off, and more especially upon all kinds of fencing, for the temporary or permanent enclosure of land, by Mr. Somerville (Com. Board of Agr. vol. ii. p. 1); he advocates the more general hurdling off of grass lands in the spring of the year.

There are two modes of folding, which should be practised according to circumstances: the first is where the sheep fed during the day on waste or common land, are penned at night, for the sake of their manure, on the enclosed arable pastures of the farm. This is a highly profitable mode. It is calculated that the dressing thus given by 500 sheep is sufficient, in a week, for one acre of land, and is worth three pounds. Hence the enhanced value of farms having ready access to down, or possessing a right of common. The second mode of folding is the feeding off of green crops by sheep enclosed in daily divisions, by hurdles, by which means the land has the full benefit, equally distributed, yielded by the consumption of the green crop; of course the value of the folding will mainly depend, both in quality and quantity, upon the food consumed: hence, too, the superior fertilizing effect derived from sheep having oil-cake or corn added to their green food. The plan of feeding sheep on one field during the day, and folding them on another during the night, is a bad practice long since condemned by Arthur Young, who describes it as "merely robbing Peter to pay Paul," since it is, in fact, only the removal from one field to another of the richest organic matters, the sheep being also injured by the driff or labour of removal, and by the fasting (so contrary to their natural habits) during the night.

The folding of sheep on green crops is one of the great moderm agricultural improvements.
HYDROGEN.

HYDROGEN. A chemical element, which derives its name from two Greek words that signify “a generator of water,” because it is one of the constituents of that fluid, which is always formed when hydrogen gas is burned in combination with atmospheric air, or with oxygen gas. It is known to us, in its simplest form, only in the state of gas, and is speedily fatal to animal life when it is breathed unmixed with atmospheric air. It is, however, a component of animal matters, and it forms a very essential part in the economy of vegetable substances, in which it is always found. Thus sugar contains 690 per cent of hydrogen; gum, 6-93; bee’s wax, 12-672; wood of the oak, 5-69; wheat starch, 0-77; acetic acid (the acid of vinegar), 6-35 per cent. It is regarded as an element, because it has resisted every attempt to decompose it. It is the lightest of all ponderable matter, 100 cubic inches weighing only 2-15 grains. No known degree of cold has been able to condense it to a liquid. It cannot support combustion, but is combustible in conjunction with atmospheric air. It constitutes one-ninth of the weight of water,—a substance essential to vegetation, and which plants are supposed to have the power of decomposing. Liebig asserts that 8-94 parts of hydrogen unite with 100 parts of carbonic acid to form woody fibre, whilst the oxygen is separated in the gaseous state. (Organic Chem. p. 63.) Most vegetable structures contain hydrogen in the form of water, but the hydrogen essential to this constitution cannot exist in the form of water. That hydrogen gas exerts a considerable influence upon the leaves of plants, was first noticed by Dr. Priestley. Sennebier found that plants which lose their green colour in the dark, preserve it under those circumstances, if a small portion of hydrogen gas is present in the atmosphere in which they are placed; and Dr. Ingenhous noticed that its presence, when they are growing in the light, renders their colour of a deeper green (Ann. de Chem. vol. iii. p. 57); and, again, M. Humboldt has noticed that the Poa annua, Trifolium arvense, and other plants growing in the galleries of coal mines, preserve their green colour, although vegetating in the dark, and that, in such situations, the atmosphere contains a proportion of hydrogen gas.

When applied to the roots of plants in moderate proportion, the influence of hydrogen gas is evidently beneficial in all those situations where this gas is evolved, as in drains, stagnant waters, dung-hills; and the vegetation growing over such places is uncommonly rank and luxuriant. The gas observed to arise by the agitation of the mud of stagnant pools is the same gas employed for the purposes of illumination, or carburetted hydrogen gas, a peculiar gas composed of carbon 0-416; hydrogen 0-0691. In the process of purification, a quantity of water exactly corresponding to that of the hydrogen, is formed by the extraction of oxygen from the air; while all the oxygen of the organic matter is returned to the atmosphere in the form of carbonic acid. Now the process of vegetable assimilation consists in the extraction of hydrogen from water, and carbon from the carbonic acid; hence the advantage of decomposing vegetable matter to living plants. A small portion of carburetted hydrogen gas in the atmosphere, or in the soil of plants, certainly therefore promotes their vegetation; but like pure hydrogen gas, when it constitutes their entire atmosphere, it destroys them. (Thomson’s Chem. iv. p. 347.)

See Gases, Their Use to Vegetation.

HYGROMETER (Gr. ὑγρός, moist, and μέτρον, measure). An instrument which indicates the degree of moisture or vapour present in the atmosphere, or its relative degrees of dampness and dryness. Hygrometers are of several forms, and a rude hygrometer is easily made by means of a long hair, or strip of leather, or cat-gut, suspended from a peg, kept in its upright position by a slight weight; these, by their very sensible contractions and expansion according to the humidity of the air, indicate, by an attached scale, its variations. Hygrometers of this kind, however, are defective, from the irregularity of their action, and the impossibility of comparing them with each other, their alteration by time, and other circumstances. These disadvantages gave rise to the construction, by Professor Daniel, of that now commonly used in England, and called by his name. This instrument is, however, somewhat complex and costly, requiring considerable skill in its use. It will doubtless be superseded by other contrivances for ascertaining the precise quantity of moisture in air, one of which, invented by Prof. A. D. Bache, of Philadelphia, has been already described under the head of DEW.

The dew-point is the temperature immediately below that of the vapour contained in the surrounding atmosphere: the difference, however, between the dew-point and that of the vapour is so slight, that for all ordinary purposes they may be considered the same.

The temperature of the invisible vapour of the atmosphere being thus ascertained (for it differs materially from the temperature of the air in which it is contained), it is easy to calculate the force it exerts as thus existing in the state of steam, and the weight of a given bulk of it. Tables have been formed showing the proportion of watery vapour in each cubic foot of atmospheric air corresponding to every degree of the dew-point.

HYSSOP. (Hyssopus officinalis, probably from the Hebrew). There are three varieties, distinguished by the colour of the flowers, the white, red, and blue; the last of which is most commonly cultivated. It is a perennial, native of Siberia. The root is knobbed, woody, fibrous; the stem about two feet high, quadrangular, erect, branching. A dry soil is the one most appropriate for hyssop. If it is grown on a rich or wet one, it becomes luxuriant; but, from a deficiency of woody matter, is generally destroyed by the frost, as well as rendered less aromatic and powerful in its medicinal qualities. It is propagated by seed and slips of the branches and young shoots, as well as by offsets. The seed may be sown from the close of February until the end of May. Rooted offsets may be planted in March, April, August, and September; cuttings of the branches in April and May; and slips of young shoots in June or July.
ICE-HOUSE.

The seeds may be inserted broadcast, or preferably in drills, six inches apart, in either case not being buried deeper than half an inch. It is the usual practice, when the seedlings have attained the growth of six weeks, to prick them out 12 inches apart; but it is by much the best practice to raise them where they are to remain.

The slips and offsets are best planted at first in a shady or north border; they are generally firmly rooted in two months.

In September or October they are all fit for removal to their final stations. After every removal, whether of planting, prickling, &c., they must be watered plentifully and regularly until established. Hyssop possesses some excitant and tonic powers, but is now rarely employed in medicine.

I.

ICE (Sax. 1r; Dutch, ijs). Water in a state of congelation. Ice is about one-eighth part lighter than fresh water; hence it swells in that element; and, owing to this property, the icebergs and ice-islands are floated down to southern latitudes from the arctic circle. Water, which freezes at 32° Fahrenheit, suddenly expands, and consequently, when it is interposed in crevices and clefts of rocks, it separates these, and often precipitates immense masses from the tops of mountains into the adjoining valleys. This is a principle which should be kept in remembrance by the farmer in making mounds or walls of earth, for if the smallest clefts be left, the walls may be broken down and crumbled to pieces even by moderate frosts.

ICE-HOUSE. A house or vault for the preservation of ice in summer, should not be regarded as merely administering to purposes of luxury, since ice contributes so much to the convenience, comfort, and even health, as to make it almost an indispensable article of domestic economy. The effects of the excessive heat which commonly prevails in the summers of the United States, are greatly obviated by the use of ice, which not only serves for the preservation of fresh meats, butter, &c.; but in addition to these advantages and its grateful employment for assuaging common thirst, it is a powerful agent in tranquillizing the irritability of the stomach in bilious fevers and dysenteries, and relieving the pain and burning heat often attendant upon inflammations and fevers. Thus, by soothing the stomach, and removing excessive heat, iced drinks and applications restore the deranged functions of the nervous and muscular systems of the sick, whilst they refresh and invigorate persons in health so as to render them capable of enduring exercise and exertion even under circumstances calculated to produce great oppression and inconvenience.

An interesting writer, has left the following testimony in favour of ice, as a restorative and remedy in fevers, which has been abundantly corroborated by subsequent experience. "I never," says he, "was in better spirits than here in this hot country (Sicily). I believe the quantities of ice we eat, in ices, contribute to it, for I find, in a very violent heat there is no such cordial to the spirits as ice, or a draught of iced water. Its cold braces the stomach, and gives a new tone to the fibres. I knew an English lady, at Nice, soon cured of a threatening consumption, by a free indulgence in the use of ices. It is the common practice here, Sicily, to give quantities of ice-water to drink in inflammatory fevers." (Brydone.)

"The custom in Sicily and Italy," says another author, "of taking ice, is considered as a powerful remedy in many diseases. The physicians of these countries do not give many medicines; but frequently prescribe a severe regimen; and prevent the baneful effects of various diseases, by suffering the sick, for several days, to take nothing but water cooled by ice, sweet oranges, and iced fruits." (Stobjerg.)

One of the greatest advantages afforded by ice houses, is that of enabling families to preserve their butter, meat, fish, poultry, game, &c., in states of the weather which would, otherwise, quickly induce them to spoil. In no part of the world are ice-houses more essential to comfort, convenience, and health, than in the United States, and in all the northern and Middle States the winters are sufficiently cold to furnish ice of sufficient thickness to lay by for preservation. The cities of the Southern States are now regularly supplied with thick blocks of ice from New England, which not only afford a regular article of export to the West Indies, but also to Calentia!

Considering the small expense and trouble at which ice houses or vaults may be constructed, and the many advantages to be derived from them, it is surprising that any respectable country establishment should be without one.

It is considered that the simplest, and most scientific form for an ice-house, is a double cone, that is to say, two cones joined base to base, the one sunk into the earth with its point downwards, the other being a conical roof, generally of wood-work, covered with thatch and pointed at top. The entrance should be placed always on the north side, and provided with two doors some distance apart, and the spot screened from the sun by trees, shrubbery, a hill, cliff, or other barrier. The lower part may be dug about 16 feet in diameter, terminating below like the point of a sugar-loaf. Its ordinary depth, for a moderate family, may be about 24 feet. The larger the dimensions, the longer will it preserve the ice, provided it be filled.

In digging, the workmen should slope the ground progressively towards the axis of the cone, to prevent the earth falling in. This conical slope should be faced with brick or stone work about one foot thick, and jointed with Roman cement, so as to be air and water tight. A well is to be excavated at the bottom two feet wide and four deep, covered at top with an iron grating for supporting the ice, and letting the water drain away.

The upper cone may likewise be built of brick-work, and covered with thatch; such a roof would prove the most durable. Whatever kind of roof be preferred, there must be left in it an oblong passage into the interior. This porch should face the north, and be at least 8

652
feet long by 2 1/4 feet wide; and perfectly closed by a well-fitted door at each end. All round the bottom of this conical cover, a gutter should be placed to carry off the rain to a distance from the ice-house, and prevent the circumjacent ground from getting soaked with moisture.

The ice-house should have no window to admit light; but be, so to speak, hermetically sealed in every point, except at its cress-pool, which may terminate in a water-trap to prevent circulation of air.

A clear day should be selected for charging the ice-house; but before beginning to fill, a quantity of long dry straw should be laid on the bottom crosswise; and as the ice is progressively introduced, straw is to be spread against the conical sides, to prevent the ice from coming into contact with the brick or stone work. The more firmly compacted the ice, the better does it keep. No layers of straw should be stratified among the ice, for they would make its body porous. Some persons recommend to pour in a little water with the successive layers of ice, in order to fill up its small crevices, and convert the whole into one mass. This may answer well when the ice is put up very cold, as the water may then be directly frozen into a solid mass.

Over the top-layer a thick bed of straw should be spread, which is to be covered with boards surmounted with heavy stones, to close up the interstices in the straw. The inner and outer doors should never be opened at once; but the one should always be shut before the other is opened.

Dry snow well rammmed keeps equally well with hard ice, if care be taken to leave no cavities in the mass, and to secure its compactness by sprinkling a little water upon the successive charges.

To facilitate the extraction of the ice, a ladder is set up against its sloping wall at one side of the door, and left there during the season. (Ure's Dict.)

The time preferred for filling an ice-house, should, when practicable, be during the prevalence of extreme cold, or as soon after as possible, since the colder the ice when packed away, and the thicker the blocks, the longer it will last. Ice and snow can often be laid by, even in the Middle States, many degrees below 32° or the common freezing point of water. The larger the quantity of ice accumulated in one place, the slower will be the rate at which it will melt.

One of the principal objects to be kept in view in the construction of an ice-house, is to have it so that the water will pass off directly, as fast as the ice thaws. If the situation is sandy, or if you come to a layer of sand or gravel about the proper depth, no further care will be necessary; but if you find a stiff clay, rock, or earth of any kind impervious to water, you must contrive an outlet or abandon the place. This outlet may be constructed in several ways. If on the side of a hill, dig a drain and make it a right by means of a water-trap or inverted syphon; or the water may be drained into a well and pumped out; or you may sink a well in the bottom until you come to sand or gravel, and fill it up with stone. The cellar walls may be laid with stone, brick, or even lined with wood, as is most convenient or economical. A space of 8 or 10 inches is generally left between the wall and surrounding earth, which is filled in with tan, charcoal, straw, corn-stalks, or any other non-conductor of heat, the first-named article being generally preferred. A house 9 feet square in the clear, and 9 feet deep, will hold about 25 cart-loads of ice, which will be enough for a large family.

A cheap ice-house may be made thus:—Dig a cellar, say 10 feet square, and 10 feet deep. Then cut small timber from the woods the proper length, and build up in the cellar after the plan of building log-cabins, leaving a space between the logs and earth to be filled in with straw, tan, or other suitable material. Raise the wooden walls 2 or 3 feet above the surrounding ground, and heap up a bank so as to turn off the rain-water. A thatched roof is generally recommended, as the best to keep out heat, but some object to such covering as affording harbour to rats and other vermin.

The importance of keeping ice well surrounded with a non-conductor, and having the water absorbed as fast as melting takes place, is shown in the following extract from the Kentucky Farmer:—

"We take at sunrise from the ice-house, as much as will be probably wanted through the day, and cover it up in some saw-dust placed in a barrel in the dairy-house. At night, the size of any given piece is scarcely perceptibly diminished. It is a perfect charm."

In some parts of the United States where thick ice is rare, some persons pack away large quantities of snow, which, if the mass be large, and the snow dry or previously well drained, will often keep through the summer. In most seassons ice may be collected in sufficient quantities to fill ice-houses in every latitude of the Middle States. If no pond or stream of sufficient size be at hand, advantage may be taken of any little rill, which, by the ejection of a small dam, may be made to overflow a considerable space. If the water be not more than 6 or 8 inches deep it will answer every purpose.

In stowing away ice the pieces should be as square as possible, and as large as they can be got or handled. They should be placed closely together like stone in a wall, and the crevices well filled with smaller fragments. The plan sometimes recommended of pounding or crushing the large pieces is reprehensible.

ICE-FLIES.

ICE-FLIES. belonging to the natural order Hymenoptera, which includes bees, wasps, ants, saw-flies, &c. The injury caused by this whole order is so small, and the benefits derived from many of them so great, that instead of being enumerated among destructive insects, they may be pronounced the benefactors of the human race.

With regard to the ichneumon flies, they perform an important and very singular part in the economy of nature, by working the destruction of caterpillars, plant-lice, and other destructive insects. Thus they effect by piercing their bodies with a kind of sting or piercer called ovipositor, and thus laying their eggs in a living nest. Each ichneumon fly seems 3 1 2 653
to single out the larva or pupa of some particular kind of caterpillar or other insect, to which it therefore stands in the relation of parasite. The eggs hatch in due time, and the larva of the ichneumon commences feeding upon its victim, the vitals of which are soon destroyed, after which the parasite or ichneumon comes forth in due time to another state of existence.

Some of the ichneumon flies are extremely small, and confine their attacks to the eggs of other insects, which they puncture, and the little creatures produced from the latter find a sufficient quantity of food to supply all their wants within the larger eggs they occupy. The ruby-tails and cuckoo-bees lay their eggs in the provisional nests of other insects, whose young are robbed of their food by the earlier hatched intruders, and are consequently starved to death. The obligations which the farmer and society at large owe to certain parasite insects is forcibly illustrated in the case of the Hessian fly, the devastations of which are often prevented through the destruction, during a single season, of nearly a whole race by its parasite.

Professor Peck has described a minute ichneumon fly, stated by Mr. Westwood to be a species of Encyrtus, that stings the eggs of the slug-fly, and deposits in each one a single egg of its own. From this in due time a little maggot is hatched, which lives in the shell of the slug-fly’s egg, devours the contents, and afterwards is changed to a chrysalis, and then to a fly like its parent. Professor Peck found that great numbers of the eggs of the slug-fly, especially of the second hatch, were rendered abortive by this atom of existence.

In treating of the pigeon tremex (Tremex columba), which in its larva state is a destructive tree-borer, Dr. Harris observes that it is often destroyed by two kinds of ichneumon-flies, (Pimpla atrata and luator of Fabricius), which may be frequently seen thrusting their slender borers into the eggs, measuring from three to four inches in length, into the trunks of trees inhabited by the grubs of the tremex and by other wood-eating insects; and, like the female tremex, they sometimes become fastened to the trees, and die without being able to draw their borers out again.

The ichneumon flies are little busy-bodies, ever on the alert, and with untiring scrutiny continually prying into every place to find the lurking caterpillar, grub, or maggot, wherein to thrust their eggs. (Harris).

A specimen of this extensive family is represented in Pl. 15, fig. 12, in the Tragus fulvus, which commits great havoc among caterpillars and grubs. See Aphidiens, &c.

IGNIS FATUUS (Lat. vain or foolish fire; a translation of the French feu follet.) A kind of luminous meteor, which flits about in the air a little above the surface of the earth, and appears chiefly in marshy places, or near stagnant waters, or in churchyards, during the nights of summer. There are, we are told, many instances of travellers having been decoyed by these lights into marshy places, where they have perished; and hence the names Jack-with-a-lantern, Will-with-a-wisp; the common people ascribing the appearance to the agency of evil spirits, who take this mode of alluring men to their destruction. The cause of the phenomenon does not seem to be perfectly understood; it is, however, generally supposed to be produced by the combustion of some highly inflammable gas, such as phosphorated hydrogen, which takes fire spontaneously on rising and mingling with atmospheric air.

Milton, in his Paradise Lost, b. ix. 1. 634, thus alludes to it:—

A wandering fire, Compact of anceous vapour, which the night Condenses, and the cold environ's round, Kindles through agitation to a flame. Which oft, they say, some evil spirit attends, Hovering and blazing with delusive light,

Milton and the amazed night wanderer from his way To dogs and mires, and oft through pond or pool,

There swallowed up and lost, from succour far.

IGNITION (Lat. ignis, fire). The act of setting fire to, or of taking fire, as opposed to combustion, or burning, which is a consequence of ignition. The term "spontaneous ignition" is applied to cases in which substance is set on fire without previous application of heat. This is illustrated in the burning of hay-stacks, when the hay has been put up too green; the scorching of corn-stacks from the same cause, and the taking fire of ships laden with fermentable products.

IMBRICATED. In botany, a term used in speaking of the arrangement of bodies, to denote that their parts lie partly over each other in regular order, like the tiles upon the roof of a house, as the scales upon the cup of some flower. In speaking of the activation of petals or leaves, to denote that they overlap each other at the margin without any involution. (Brandae Dict. of Science.)

IMPLEMENTs, AGRICULTURAL. Almost all the operations of agriculture may be performed by the plough, the harrow, the scythe, and the scythe; and these, or similar tools for performing the same work, are the sole implements in the primitive agriculture of all countries. With the progress of improvement, however, many other implements have been introduced, the more remarkable of which are the drill-plough, the horse-hoe, the winnowing machine, the thrashing machine, and the reaping machine. The object of all these implements and machines is to abridge human labour, and to perform the different operations to which they are applied with a greater degree of rapidity, and in a more perfect manner than before. In the present work the different implements are treated of in their alphabetical order. Of the implements in the construction of agricultural instruments in England, the judges of implements at the Liverpool meeting of the English Agricultural Society, in their report very justly remark, when speaking of the good effects which have already resulted from the public exhibition of implements at the Society's meetings, in stimulating the talent of the mechanic and the zeal of the husbandman. At Oxford the show-yard may be said to have presented an epitome of the state of agricultural mechanism existing in 1839, the era of the formation of the Royal Agricultural Society of England. No spectator of that show can have failed to be struck with surprise and admiration at the Liverpool exhibition. At Oxford there were some examples of good machinery
and workmanship, but many more of rude, cumbersome, and ill-executed implements. At Liverpool many machines were exhibited, not only of surpassing skill in contrivance and execution, but also having for their object the effecting of processes in tillage-husbandry of the most refined nature and acknowledged importance, but hitherto considered of very difficult practical attainment. Some of these may already be considered as forming part of the necessary apparatus of every well-managed farm, and to be essential to its economy and profit. This vast stride in the mechanics of agriculture, made within so short a period, has doubtless arisen from the concentration of agriculturists and mechanicians from all parts of the empire: and a still higher perfection in machinery may be confidently anticipated from the opportunity offered, under the auspices of the Society, of periodically contrasting and estimating the merits of varied implements used for similar purposes in different localities and soils. It is apparent that the manufacture of even the commoner instruments has already, to a great extent, passed out of the hands of the village ploughwright and hedge-carpenter, and been transferred to makers possessed of greater intelligence, skill, and capital. The improved style of finish, the greater lightness and elegance of construction, and the generally superior adaptation of the means to the end, in every class of implements, were sufficient manifestations of the beneficial results arising from the encouragement given by the Society to these objects. Neither were examples wanting in the higher classes of machines to show that the fourth important object for which the Society was incorporated is, to some extent, fulfilled—viz. "to encourage men of science in their attention to the improvement of agricultural implements."

The great variety of soils and fluctuations of climate in the extensive territory of the United States, call for multiplied expedients to till the various plants, and provide shelter from heat as well as cold. The wants and exigencies known in various parts of the country must therefore contribute to make the United States a fruitful field of observation; according to, by consulting the records of the Patent Office at Washington, we find that since the year 1793, when the first patent law was instituted, and up to the year 1836 inclusive, the number of patents taken out for inventions is 6000, of which 124 are for improvements in the plough,—119 for threshing-machines,—80 for churns,—125 for washing-machines, &c.

The remarks of the Messrs. Ransome, of Ipswich, upon the preservation of agricultural implements in general, are such as every farmer should be guided by. They suggest to farmers generally, that a little instruction given to the workmen in the use of the machines, and care in preserving them, would add to their efficiency and durability. Attention to washing implements and machines before laying them by, a little oil on such as have revolving wearing parts, and a coat of paint occasionally to each, will cost but little, and make the difference between having a machine ready for use, or covered with rust and wanting repair just as the season for its use commences. These suggestions are so obvious, that one would think no apology needful for making them, as experience proves that a large proportion of the repairs required arises from want of attention to these apparently trifling matters. And to this end the advice of Mr. Crosskill, of Beverley, may be acted upon with considerable advantage: he says, "Select the most likely labourer on the farm, put the implements under his care, make it a strict rule with all the men that each implement done with for the season shall be brought one particular place, say near the pond or pump; the man having charge of the implements must then wash and clean them well before putting them into the shed."

IMPOSTMUSE. In farriery a sort of swelling, or collection of matter or pus in any part of the body of an animal. See Abscess.

IN-AND-IN-BREEDING. The practice of breeding from close relations. See Breeding, cattle, sheep, &c.

INCH. A measure of length, the twelfth part of a foot.

INCISORS or INCISORES (Lat. incido, I cut). The teeth implanted in the inter-maxillary bones of the upper jaw, and in the corresponding place in the lower jaw, and which are generally shaped for the purpose of cutting or coarsely dividing the food. The ruminating animals, including the bull and cow, sheep, goats, the deer tribe, and the camel have no incisors in the upper jaw; but some of them have canine teeth, which project from the mouth. See Age of Animals.

INCLOSURE (Lat. includo, I shut up). See Enclosure.

INCUBATION (Lat. inceumbo, I brood over). Hatching or the laying down of an animal upon her own or another's eggs, communicating to them heat, and maintaining them at her own temperature, a condition essential to their development. In many animals the development of the fetus takes place after the exclusion of the egg, and whilst it is maintained in contact with the external surface of the parent's body, as in the crab and lobster tribes; or agglutinated to the surface of the abdomen, as in certain species of pipe-fish (syngnathus), or concealed in cutaneous marsupial cavities, as in other species of syngnathus, and the hippocampus; but in these and other instances from the cold-blooded animals, the eggs are retained by special contrivances in contact with the parent, without occasioning any restraint upon her postures or movements.

That a due degree of warmth is the essential object of incubation in birds is proved by the ancient and well-known practice of substituting artificial heat, by which fertile eggs are hatched in the same period, and the excluded chick is as fully and strongly developed as when produced by natural incubation. Artificial incubation has been practised from a remote period by the Egyptians and Chinese; the former, indeed, have carried this process to such a high degree of perfection, as in many instances to have entirely superseded the use of the hen in hatching.
INCUBATION.

INDIA, AGRICULTURE OF.

It is effected either by means of an oven, stove, or steam, and it has been calculated that the ovens of Egypt every year communicate life to about 93,000,000 chickens. This process has received considerable attention from the French philosophers; but perhaps the best exemplification of its results, that has been written upon, was given by the proprietor of the Ecalabion, which was lately exhibited in Pall Mall, London.

The mean temperature of incubation is 100° Fahr.; it may vary from 95° to 105°, and towards the close of the process may be suspended for one or two hours, or for a longer period, according to the degree of extraneous heat which the eggs may derive from their situation, without fatal consequences to the embryo. The power of communicating the requisite degree of warmth to their eggs arises out of the unusual development of, and determination of blood to, a peculiar plexus of vessels, distributed over the skin of the abdomen, and which, in most birds, is connected with a derivation of blood from the internal organs of generation after the subsidence of the functional activity of the ovarium and oviduct to the external integuments. The vascular, hot, and sensitive condition of the skin of the abdomen is the exciting cause of that uncontrollable propensity to incubate, which the Greeks denominated "storage," and which, with its associated phenomena of patience, abstinence, and self-denial, forms so remarkable a feature in the economy of birds. The eggs of the bird present several peculiarities in relation to the circumstances under which the foetus is to be developed; their oval form permits a greater proportion of their surface to be in contact with the heat-communicating skin of the parent, than if they had been a spherical body; while the shell, by virtue of its hard, calcareous texture, and its arched disposition about the soft contents, sufficiently defends them from the superincumbent pressure. As warmth is the only essential influence which the egg derives from the parent, the shell is porous and permeable to air, and the germ is surrounded by an adequate store of nutritious matter. See Egg.

The period of incubation is generally directly as the size of the bird, but the degree of development which the chick attains prior to incubation varies. As a general rule, it is inferior in birds of flight, as the Accipitrine and Passerine orders, than in the terrestrial, wading, and swimming birds; and the warmth and complexity of the nest bears relation to this difference of development. If the thrush had been forewarned that her young would be excluded from the egg naked and helpless, she could not have prepared beforehand a warmer and more comfortable abode than her instinct had led her to construct for their accommodation; and if with such a nest we contrast the rude mass of straw in which the hen deposits and incubates her eggs, it might be imagined that she knew beforehand that her chickens would come into the world well clothed and strong enough at once to run about and pick up their own food. In this case, therefore, the nest relates only to incubation; in the other, to incubation and subsequent rearing of the young; and according to the degrees of development attained during incubation, and the associated condition of the nest and habits of the parent, birds have been divided into two great groups, the Aves aterras and Aves procellae. (Brandel's Dict. of Science.)

INDIA, THE AGRICULTURE OF. The British farmer will, I am afraid, not derive many useful hints from the most careful study of the agriculture of the eastern portions of Asia. In Hindostan, for instance, too many causes have contributed to retard the march of agricultural improvement. The innate dislike of the natives to innovations of all kinds, the nature of their region, their indolence, and the political oppressions under which they have long been labouring, are amongst the many causes of the degraded state of Indian agriculture. I am indebted to my brother, Mr. George Johnson, of the Supreme Court of Calcutta, for most of the following sketches of Indian modes of cultivation. He says, in describing the residences of the Indian ryots or farmers, "When I speak of an Indian farm, the image must not rise to the mind of the European reader of a substantial dwelling-house, surrounded by commodious outbuildings, and conveniently placed amongst its compactly enclosed fields; such an agricultural establishment bespeaks a far advance in the art of cultivation, the employment of large capitals, and remunerating prices to the cultivator. Now, none of these contingencies occur in Hindostan; but, on the contrary, the operations of agriculture are rudely executed; the cultivators are poor, the profits are small, the results correspondent. The dwellings of the ryot throughout India are in no degree superior to the other mean huts with which they are associated in the village. No barn is attached to the residence of the poorer cultivators, for the pittance of grain annually raised is immediately beaten out—the major part sold at once to the merchant, and the small residue for seed and sustenance is stored in baskets or jars, and these are usually placed in the room where the family dwells. The outbuildings rarely extend beyond an enclosure in which to secure the cattle at night. By far the greatest number of farms do not exceed a size requiring a single yoke of oxen, for the occupier is the only ploughman."

The various imposts to which these little farmers are exposed, sound strange to English agriculturists; they are enumerated by Dr. Buchanan. (Ind. Rech. vol. ii. p. 200.) The ryot's heap of grain is usually about 3000 seers: of this is first set apart—

| For the gods, or rather for the priests | 5 |
| For charity to the brahmins and other mendicants | 10 |
| For the astrologer | 1 |
| For the hereditary brahmin of the village | 2 |
| For the priest | 2 |
| For the potter | 1 |
| For the carpenter and blacksmith | 2 |
| For the washerwoman | 2 |
| For the beadle | 7 |
| For the chief of the village | 53 |
| For the accountant | 200 |
| For the watchman | 30 |
| For the conductor of the water | 314 |
INDIA, AGRICULTURE OP.

This leaves a residue of 2636 seers; of this government takes 10 per cent., and, after all the drains have been satisfied, the grower is left in possession of a residue of two thousand seers of rice. (Buchanan's Myore, vol. i. p. 2.)

Irrigation is practised in India, and in almost all the hot countries of Asia, to an extent of which the English farmer has little conception; for, as Mr. George Johnson remarks, "In every district of Hindostan, as in all other tropical climates, irrigation is the most effectual mode of promoting fertility. In places favoured by nature, whole plains are occasionally flooded merely by the construction of a dam across the outlet of some mountain stream, or it is confined nearer to its source, so as to form a reservoir, from which the water may be obtained at the most desirable seasons. In less favourable situations, the water frequently has to be raised to a considerable height, in order to attain an elevation level with, or slightly above the cultivated land. This is very generally effected by a scoop of matting suspended between two ropes, the ends of which are held by two men who bale it from the reservoir into a hole some feet above it, and from thence it is similarly baled by others, from hole to hole, until the desired height is attained. Sometimes the scoop is suspended between poles erected in the form of a gallows; at others, as in the Jut wells, from which the water is raised by cattle or by hand in some districts. The extensive canals formed in the neighbourhood of Delhi and in the Punjab are no longer employed. The machinery, so general in China, is nowhere used in India for raising water. In 1798, Dr. Tennent relates, that the practice of the natives then was, and is still followed, after ploughing the fields in the usual manner, but before sowing, to divide them into regular small squares, like a chessboard; each square is surrounded with a shelving border about four inches high, capable of preventing the escape of water. Between these square enclosures, small dykes are formed for conveying a rivulet over the whole field; when the water has stood a sufficient time in one square, it is let off into the surrounding dyke, and conveyed to another, and so on in succession through the whole field. The fertility induced amply recompenses the labour, and the neatness imparted to the country by this husbandry is very striking." (Ind. Reck. li. 167.) In some places the water has to be raised from deep wells, several of which are in the most elevated parts of each field. The work of drawing the water is performed by two bullocks, not travelling round in a mill, but pacing in a line direct from the well's mouth. The various little trenches already mentioned, all radiate from these wells. About Panna the irrigation water is raised from the wells by means of a bamboo lever, with its leaves as a rope about 10 feet high, a weight at the opposite end being employed to assist the workmen in counterpoising the leather bag of water; this plan is only resorted to when the wells are shallow, and the water near the surface of the earth, and then not bags but buckets are used, sometimes of leather, but more frequently of iron. Four bullocks and three labourers are engaged nine days in irrigating one acre of land thoroughly. The importance of this branch of agriculture is evidenced by the great number of wells, which in these most indolent people sink in districts deficient in streams. Near Madras, at Saymbrunhacum, a reservoir more than 7 miles long and 3 broad, for the purposes of irrigation, has been formed by merely raising a bank across a natural ravine. In the Tamil language a reservoir of this kind is called an Eray. This supplies 32 villages containing 5000 persons employed in agriculture (should the rains fail) for 18 months. Sluices lined with bricks pass under the banks to supply the fields; the inner opening of the sluice is covered by a flat stone, in which is cut a circular hole, through which the water is allowed to pass as required, by means of a plug fixed to a bamboo, and secured from escape by means of stone pillars and cross-bars. When bullocks are employed to raise water from wells, a leathern bucket is used which holds 45 gallons; this two bullocks will raise every minute and a half from a well 44 feet deep, and they work eight hours per day.

To the insoluble matter of the water employed in irrigation, must be attributed a considerable portion of its value. These vary at different seasons. That of the Ganges, which is extensively employed in irrigation, was examined by Mr. Everett. He found in it of insoluble matters—

As these rich, purely divided matters, are depositing on the lower grounds within reach of the flood waters, it follows as a natural consequence that "the higher soils are generally and rapidly impoverishing, and this to a degree of which few, who have not made the subject of attention, are aware."

The rapid effects produced by a copious artificial watering of grass lands under the burning sun of India, may be judged by the following report made in 1841, by Sir Edward Burnes to Lord Auckland, upon the artificial grasses of Cabool.

"There are three kinds of grasses cultivated in Cabool—rishku,' or lucern, 'shufu,' a kind of trefoil, and 'si barga,' or clover. The first
and the last continue to yield crops for some years, but the 'trefoil' (shufu) is an annual. The lucern (rishkut) is sown in spring, generally about the vernal equinox; for each jureeb, or about half an English acre of Cabool, or about 28 lbs. English, are required as seed. In 40 days it comes to perfection, and is cut down, and will yield 4 full-grown crops ere winter sets in, but by early cutting 6 or 8 crops may be drawn; the last may sometimes be inferior from premature cold. One jureeb or half an English acre yields on an average ten camel loads of grass at each cutting, as a camel carries about 500 lbs.; this is a produce of 5000 lbs. the jureeb, or 10,000 lbs. the English acre, and for four fine crops 40,000 lbs. English. The third crop is considered the best, and from it the seed is preserved: of this the half acre sown with the two seers of Cabool will yield 40 seers, or about 560 lbs. This plant requires the best black soil, much manure, and is watered 5 times each crop—in fact whenever it droops. It is sometimes sown along with barley, but in that case the grain, by exhausting the soil, injures the crop. The seed is never exported, but the grass is so potent and full the cattle feed on it, that much to exceed the consumption; it is, therefore, dried, and that produced at any distance from a market is generally stored in this manner, and sold during winter. A camel load of it, or about 500 lbs. English, whether green or dry, sells for one Cabool rupee, a coinage of which 115 are equal to 100 Company's rupees. Lucern generally lasts for 6 years, but it will yield for 10 years if manure be abundantly scattered over it. The seed is at present sold for a rupee, a stone of 14 lbs.; but as it is not cultivated, for exportation, this is much dearer than it might otherwise be had, and its price has been almost doubled by the arrival of the British troops. The trefoil or 'shufu' in cultivation, in the time of sowing, reaping, and soil, resembles lucern, and the calculations of produce for the one will suffice for the other, only it is an annual plant. The seed, too, is dearer by one half than that of lucern.

"The clover or 'si barga' (i.e. three leaves), assimilates likewise to the lucern, and it lasts as long. I may, however, observe, that the climate of Cabool is much later than that of England, and, excepting the seed sown in autumn, nothing is put in the ground here with advantage before the 1st of April."

Of a rotation of crops, or of fallows, the ryots of Bengal have but little idea: their richest low-lying grounds are devoted to the growth of rice, and on the uplands they generally crop the soil till it is exhausted, and then abandon it to the weeds, which soon occupy it in profusion: they have, besides, a wretched method of sowing various seeds together, in a manner that cannot be sufficiently reprehended. It is only in some parts of India that any thing like rotation of crops is observed. In the highlands of Behar, the following rotation is usually adopted:—1. Year-fallow and wheat; 2. Maize (muckai), followed by big or bear, a kind of barley; 3. Murwa, sama, and cowaroe, being species of millet, followed by cotton.

There is nothing remarkable in the domestic animals of Bengal: the oxen are inferior, and their sheep are described as "small, lank, and thin:" the colour of three-fourths of each flock is black or dark-gray. The quality of the fleece is worse, if possible, than its colour; it is harsh, thin, and hairy, in a very remarkable degree: no part of clothing or domestic furniture, so far as Dr. Tennant had observed, is manufactured of wool, except a coarse kind of blanketing which some of the boatmen (dandies) and people in the upper districts use during the cold season, as a wrapper at night.

The same system of irrigation which prevails in Arabia, in Persia, and in Hindostan, is carried on to a very considerable extent in the empire of China, where the soil is cultivated perhaps more carefully, and with a greater minuteness of detail, or garden system of husbandry, than in any other country. I do not allude in this work to their cultivation of crops such as the tea plant, or those from which the English cultivator is as little likely to derive useful hints. They are remarkable for the care with which they deepen, even by the spade, their cultivated lands, and their husbanding of manures of all kinds is admirable; even the thing that is produced in their cities ended up is collected as fertilizing properties, is collected and preserved with the utmost care. The night-soil, for instance, is made into a kind of bricks with calcareous matter, and carried into the most distant provinces, for the use of the farmers. "There is, perhaps," says the author of 'Trivial Husbandry' (vol. i. p. 273), "no part of the world in which the preparation and the practical application of vegetable and animal manure is so well understood as in China; but, owing to its overflowing population, almost the whole of the labour is performed by man, by which the number of working animals is so much reduced, that night-soil forms the principal dependence of the farmer. It is extensively employed in a dried state, and is sold as an article of commerce throughout the empire, in the form of cakes, mixed up with one-third of their weight of marl." To the same end the poor are employed in collecting in the public roads and streets all the horse and other dung, which is also made into cakes with marl, and these are afterwards dried in the sun.

The system of tillage formed by the Chinese, however antiquated, is not of a general description, calculated to instruct the English cultivator; and the Chinese husbandmen are entirely un instructed as to any scientific principles, by the observance of which the cultivation of the earth is improved. The same remark, in fact, extends to most oriental farmers: they merely follow a regular routine of operations, because it is that which their forefathers adopted: followed without consideration, it is transmitted unimproved. See Irrigation, and Night-soil. (Memoir on the Agriculture of India, by G. W. Johnston.)

INDIAN CORN. See Maize.

INDIAN CRESS. See Cress, Indian.

INDIAN MILLET (Sorghum vulgare). Sorgli is the Indian name, according to Bauhin. The French call it grand millet, the Italians saggsena or sorge, and the Spaniards alvacuda. It is much cultivated in Arabia and most
INDIAN RUBBER.

parts of Asia Minor, and has been introduced into Italy, Spain, Switzerland, and some parts of Germany; also into China, Cochín-China, and the West Indies, where it grows commonly five or six feet high or more, and, being esteemed a hearty food for labourers, is called Negro Guinea corn. Its long awns or bristles defend it from the birds. In England, the autumns are seldom dry and warm enough to ripen the seeds well in the field. In Arabia it is called dora or durra. The flour is very white, and they make good bread of it, or rather cakes, about two inches in thickness. The bread of it in some parts of Italy is dark and coarse. In Tuscany it is used chiefly for feeding poultry and pigeons; sometimes for kine, swine, and horses. Brooms are made of the spikes, which are also sent to England for the same purpose. The Indian millet, as well as the common sort (panicum) is cultivated in some parts of North America, and has been tried in England, but it is only in the warmest autumns that it ripens its seeds. (Loudon's Encyclopaedia of Plants.) See GUINEA CORN.

INDIAN RUBBER. Gum Elastic, or Caoutchouc, is a well-known tough and yielding substance, obtained in South America and Java from the sap of a tree called the Siphonia calacuna. To procure the sap, incisions are made through the bark in many places, and the milky juice which exudes is spread over clay moulds, and dried in the sun, or by fire, the smoke from which last blackens it.

The juice itself has been of late years imported. It is of a pale-yellow colour, and has the consistence of cream. It becomes covered, in the bottles containing it, with a pellicle of concrete caoutchouc. Its specific gravity is 1·012. When it is dried, it loses 55 per cent. of its weight: the residuary 45 is elastic gum. When the juice is heated, it immediately coagulates, in virtue of its albumen, and the elastic gum rises to the surface. It mixes with water in any proportion; and, when thus diluted, it coagulates with heat and alcohol as before.

The specific gravity of caoutchouc is 0·925, and it is not permanently increased by any degree which they make of it in some parts of India, nor does it become hard and stiff. By long boiling in water it softens, swells, and becomes more readily soluble in its peculiar menstrua, but when exposed to the air, it speedily resumes its pristine consistence and volume. It is quite insoluble in alcohol; but in ether, deprived of alcohol by washing with water, it readily dissolves, and affords a colourless solution. When the ether is evaporated, the caoutchouc becomes again solid, but is somewhat clammy for a while. When treated with hot naphtha, distilled from native petroleum, or from coal-tar, it swells to 80 times its former bulk; and if then triturated with a pestle, and pressed through a sieve, it affords a homogeneous varnish, which being applied by a flat edge of metal or wood to cloth, prepares it for forming the patent water-proof cloth of Mackintosh.

Two surfaces of cloth, to which several coats of the above varnish have been applied, are, when partially dried, brought evenly in contact, and then passed between rollers, in order to condense and smooth them together. This double cloth is afterwards suspended in a stove-room to dry, and to discharge the disagreeable odour of the naphtha.

Caoutchouc dissolves in the fixed oils, such as linseed oil, but the varnish has not the property of becoming concrete upon exposure to air. It is more or less soluble in the oils of lavender and sassafras.

It melts at 248° Fahrenheit, and stands afterwards a much higher heat without undergoing any further change. When the melted caoutchouc is exposed upon the surface of the air, it becomes hard on the surface in the course of a year. When kindled, it burns with a bright flame and a great deal of smoke.

Neither chlorine, sulphurous acid gas, muriatic acid gas, ammonia, nor fluosilicic acid gas affects it, whence it forms very valuable flexible tubes for pneumatic chemistry. Cold sulphuric acid does not readily decompose it, nor does nitric acid, unless it is somewhat strong. The strongest caustic potash ley does not dissolve it, even at boiling heat.

Mr. William Henry Barnard, in the course of some experiments upon the impregnation of ropes with caoutchouc, at the factory of Messrs. Enderby, at Greenwich, discovered that when this substance was exposed to a heat of about 600° Fahrenheit, it resolved itself into a vapour, which, by proper refrigeratory methods, was condensable into a liquid possessing very remarkable properties, to which the name caoutchoucine has been given. For this invention "of a solvent not hitherto used in the arts," Mr. Barnard obtained a patent, in August, 1833. His process for preparing it is described in his specification as follows:

"I take a mass of the said caoutchouc, or Indian rubber, as imported, and having cut it into small lumps, containing about two cubic inches each (which I prefer), I throw these lumps into a cast-iron still. I then apply heat to the still in the usual manner, which heat is increased until the thermometer ranges at 600 degrees of Fahrenheit, or thereabouts. And as the thermometer ranges progressively upwards to 600 degrees of Fahrenheit, a dark-coloured liquid is distilled over, which I claim as my said invention, such liquid being a solvent of caoutchouc, and other resinous and oleaginous substances. When the thermometer reaches 600 degrees, or thereabouts, nothing is left in the still but dirt and charcoal.

"I afterwards subject the dark-coloured liquid thus distilled to the ordinary process of rectification, and thereby obtain fluids varying in specific gravity, of which the lightest hitherto has not been under 670, taking distilled water at 1000, which fluids I also claim as my said invention.

"At each rectification the colour of the liquid becomes more bright and transparent, until, at the specific gravity of 680, or thereabouts, it is colourless and highly volatile.

"In the process of rectification (for the purpose of obtaining a larger product of the oil colourless) I put about one-third of water into the still. In each and every state the liquid is a solvent of caoutchouc, and several resinous and oleaginous substances, and also of other
substances (such as copal), in combination with very strong alcohol."

The discovery of the chemical solvent which forms the subject of the patent above described, has excited considerable interest in the philosophic world, not only from its probable usefulness as a new article of commerce, but also from two very extraordinary characteristics which it is found to possess, viz., that, in a liquid state, it has less specific gravity than any other liquid known to chemists, being considerably lighter than sulphuric ether, and, in a state of a vapor, is heavier than the most ponderous of the gases.

Its elementary constituents are,

This new material (when mixed with alcohol) is a solvent of all the resins, and particularly of copal, which it dissolves, without artificial heat, at the ordinary temperature of the atmosphere; a property possessed by no other solvent hitherto discovered and hence it is peculiarly useful for making varnishes in general. It also mixes readily with oils, and will be found to be a valuable and cheap menstruum for liquefying oil-paints; and, without in the slightest degree affecting the most delicate colours, will, from its ready evaporation, cause the paint to dry almost instantly.

Cocoa-nut oil, at the common temperature of the atmosphere, always assumes a concrete form; but a portion of this caoutchoucine mixed with it will cause the oil to become fluid, and to retain sufficient fluidity to burn in a common lamp with extraordinary brilliancy.

Caoutchoucine is extremely volatile; and yet its vapour is so exceedingly heavy that it may be poured, without the liquor, from one vessel into another, like water. (Ur's Dict.)

INDIAN TOBACCO. See Eye-bright.

INDIAN TURNIP (Arum triphyllum), Wake-robín, &c. An American plant, distinguished by its head of beautiful red berries growing upon a single stem, and its perennial bulbous root, resembling a small rough turnip, possessing such an extremely acrid juice as, when bitten or chewed, causes violent inflammation in the mouth and salivary glands, inducing copious salvation. This acrid quality of the root is, however, dissipated by boiling or drying. The dried root, grated and boiled in milk, is a popular remedy for coughs and pulmonary consumption.

The English wake-robín, or cuckoo-pint, is the Arum maculatum, which in many of its sensible qualities resembles the American Indian turnip.

INDIGENOUS PLANTS. Such plants as are natives of or are common to a country.

INDIGO (Indigofera, from indigo, a blue dye-stuff, a corruption of Indicum, India, and fero, to bear; most of the species produce the well-known dye called indigo, the finest of all vegetable blues). This is an extensive genus of rather elegant plants, the shrubby kinds of which are well worthy of cultivation. The stove and greenhouse shrubby kinds thrive best in a mixture of sandy loam and peat, and may be increased without difficulty by cuttings of the young wood, planted in sand, under a glass, in heat. The annual and biennial kinds must be raised from seeds sown in a hotbed in spring; and when the plants have grown a sufficient height, they may be planted singly into pots, and treated as other tender annuals and biennials. The genus belongs to the natural order Leguminosae; hence the flowers resemble the pea tribe. The vellum is round, emarginate; the keel furnished with a subulate spur on both sides; stamens didaephalous; style filiform; legume continuous, one or more seeded, two-valved. The Indigofera cordata yields the finest indigo; the I. angustifolia, an inferior kind, which comes from Egypt; the I. tinctoria, besides yielding indigo, is also medicinally employed; and the powdered leaf of I. anil is used in some diseases of the liver. (Paxton.)

Indigo, when cultivated, thrives best in a free, rich soil, and a warm situation, frequently refreshed with moisture. The usual course pursued for its culture is as follows:—

Having first chosen a proper piece of ground, and cleared it, hoe it into little trenches, not more than one inch deep, nor more than fifteen inches asunder. In the bottom of these, at any season of the year, stew the seeds pretty thick, and immediately cover them. As the plants shoot, they should be frequently weeded, and kept constantly clean, until they spread sufficiently to cover the ground. Those who cultivate great quantities, only stew the seeds pretty thick in little shallow pits, hoed up irregularly, but generally within four, five, or six inches of one another, and covered as before. Plants raised in this manner are observed to answer as well as the others, or rather better; but they require more care in the weeding. They grow to full perfection in two or three months, and are observed to answer best when cut in full blossom. The plants are cut with reaping-hooks, a few inches above the root, tied in loads, carried to the works, and laid by strata in the steeper. Seventeen negroes are sufficient to manage twenty acres of indigo; and one acre of rich land, well planted, will, with good seasons and proper management, yield five hundred pounds of indigo in twelve months; for the plant ratoons (stools, stoles, or tillers, i.e. it sends out stolones, or new growths), and gives four or five crops a year, but must be replanted afterwards. (Brown.)

The process by which the blue colouring matter is extracted from the plant in Mexico, the East Indies, &c., is as follows:—

The leaves are gathered at maturity, and immersed in vessels filled with water till fermentation takes place. The water then becomes opaque and green, exhaling an odour like that of volatile alkali, and evolving bubbles of carbonic acid gas. When the fermentation has been continued long enough, the liquid is decanted and put into other vessels, where it is agitated till blue flakes begin to appear. Water is now poured in, and flakes are precipitated in the form of a blue powderly sediment, which is obtained by decantation, and which, after being made up into small lumps and dried in the shade, is the indigo of the shops. It is insoluble in water, though slightly soluble in alcohol; but its true solvent is sulphuric acid, with which it forms a fine blue dye, known by
the name of liquid blue. It affords by distilla-

carbonic acid gas, water, ammonia, some

carbuncle, and much charcoal; whence its constituent principles are most

probably carbon, hydrogen, oxygen, and nitrogen. Indigo may be procured also from several other plants besides Indigofera tinctoria, and particularly from Isatis tinctoria, or woad, a plant indigenus to Britain, and thought to be the plant with the juice of which the ancient Britons stained their naked bodies, to make them look terrible to their enemies. If this plant is digested in alcohol, and the solution evaporated, white crystalline grains, somewhat resembling starch, will be left behind; which grains are indigo, becoming gradually blue by the action of the atmosphere. The blue colour of indigo, therefore, is owing to its combination with oxygen.

Indigo is not cultivated to so great an extent in the United States as formerly, the imported article being obtained so readily. The following processes for indigo are universal, and are in quantities for family use extracted from the Southern Agriculturist.—Cut the indigo when the under leaves begin to dry, and while the dew is on them in the morning; put them in a barrel, and fill this with rain water, and place weights on to keep it under water; when bubbles begin to form on the top, and the water begins to look of a reddish colour, it is soaked enough, and must be taken out, taking care to wring and squeeze the leaves well, so as to obtain all the strength of the plant; it must then be churned (which may be done by means of a tolerably open basket, with a handle to raise it up and down) until the liquor is quite in a foam. To ascertain whether it is done enough, take out a spoonful in a plate, and put a small quantity of very strong lye to it. If it curdles, the indigo is churned enough, and you must proceed to break the liquor in the barrel in the same way, by putting in lye, (which must be as strong as possible,) by small quantities, and continuing to churn until it is all sufficiently curdled; care must be taken not to put in too much lye, as that will spoil it. When it curdles freely with the lye, it must be sprinkled well over the top with oil, which immediately causes the foam to subside, after which it must stand till the indigo settles to the bottom of the barrel. This may be discovered by the appearance of the water, which must be let off gradually by boring holes first near the top and afterwards lower, as it continues to settle; when the water is all let off and nothing remains but the mud, take that and put it in a bag; (flannel is the best) and hang it up to dry, afterwards spreading it dry on large dishes. Take care that none of the foam, which is the strength of the weed, escapes; but if it rises too high sprinkle oil on it.

Seven or eight species of indigo are found in the United States, most of which are in the south. The wild indigo (Dyer's Butilus), common in Pennsylvania and other Middle States, yields a considerable proportion of blue coloring matter of an inferior kind. (Flora Cernua.)

INDURATED (Lat. indurare). A term implying that a substance naturally soft is hardened.

It is a term frequently used in botanical works to signify the above-mentioned change.

INERT VEGETABLE MATTER. The inert vegetable matters of the soil are those which decompose very slowly, and consequently afford very little nourishment to the growing plant. Of this kind are woody fibre, tanner's bark, peat, &c., all of which, if not previously rendered more easily soluble by being mixed with farm-yard dung, or other easily fermentable substances, afford food to vegetation by very slow degrees.

INFIRMARY (Lat. infirmus, weak). An hospital for the reception of the sick. The Veterinary College in London have an infirmary for sick and diseased horses, to which the horses of their subscribers have access and medical treatment, free from charge.

INFAMATION. In farriery, is a disease or affection consisting in an increased heat and action in any part of an animal, arising from various causes, external or internal, local or universal. In animals, the chief causes are wounds, bruises, and sudden or excessive cold, and the application of heat afterwards.

The horse is subject to inflammation of the lungs, stomach, bowels, kidney, and of the eye and foot. Of inflammation of the bowels I have already spoken (see Bowels). Of inflammation of the stomach in the horse, except from poisonous herbs or drugs, we know little. It very rarely occurs, and then can with difficulty be distinguished from inflammation of the bowels; and in both diseases the assistance of a skilful veterinary surgeon is required.

Among the causes of inflammation of the kidney are, improper food, such as mow-burnt hay, musty oats, &c. Bleeding, in this case, must be promptly resorted to, and carried to its full extent. An active purge should next be administered; and a counter-inflammation excited as near as possible to the seat of disease.

Inflammation of the lungs is one of the causes of roaring: it is generally brought on by the respiration of heated and empoisoned air, in neglected and filthy stables; by sudden changes from heat to cold, or from cold to heat, from grass to the stable, or stable to grass, and so on. Bleeding, blistering, and relaxing medicines should be resorted to under the advice of a professional man; for the cure of this malady can scarcely be safely undertaken without proper advice.

Cooling applications, such as Goulard's extract, one drachm or half an ounce of the tincture of opium to a pint of water, with mash diet and gentle physic, will usually get rid of common inflammation of the eye, or the inflammation will subside itself; but should three or four days pass and the inflammation not be abated, we may begin to suspect that it is specific and fatal inflammation, or true ophtalmia, for which there is no cure. See Erys.

Inflammation of the foot is brought on by over-exertion. If a horse has been ridden or driven hard be suffered to stand in the cold, or if his feet be washed and not speedily dried, he is very likely to have "fever in the feet." Bleeding at the foot, and poultices of linseed meal to cover the whole of the foot and pastern, with sedative and cooling medicines, should be

3 K 661
INSECTS. resorted to. And to promote evaporation it is advisable to remove the shoe, pare the sole as thin as possible, and have the crust, and particularly the quarters, well rasped. See Grease.

For inflammation in sheep see Sheep.

In inflammatory fever in cattle, profuse bleeding, followed by immediate purging (½ lbs. of Epsom salts dissolved in water or gruel), must be had recourse to. (Younet on Cattle, p. 359.) INFLORESCENCE (Lat. inflorescere, to flourish). The general arrangement of the flowers upon a stem or branch. It consists of the following principal kinds: viz., the spike, the raceme, the panicle, the capitulum, the cyme, and the umbel.

The spike is a long rachis of flowers sessile, or without foot-stalks. The term raceme is commonly applied to flowers when they are arranged round a filiform or thread-like simple axis, each particular flower being stalked. The panicle is a loose disposition of inflorescences, in which the primary axis develops secondary axes, which themselves produce tertiary, as in oats; or, in other words, it is a raceme bearing branches of flowers in place of simple ones. Capitulum implies the arrangement in small heads. The cyme is a mode of inflorescence resembling a flattened panicle, as that of the elder.

Of the particular arrangement of the umbel, the carrot is a familiar example; the peduncles and pedicles spring from a common centre, and rise till they form a nearly flat tuft.

The difference between an umbel and a corymb is, that whilst in the latter the flowers form a flat head, the pedicels do not, as in the former, spring from a common centre. ( Paxton's Bot. Dict.; Brownie's Dict. of Science.)

INFLUENZA. An epidemic catarrh, attended by fever and other symptoms, which often run very high, and assume a variety of aspects, dependant upon the seasons and other causes. The possibility of the existence of a peculiar state of the nervous system, although we have no means of detecting it, is undoubtedly the true cause of influenzas. Miasms, or vapours of a noxious kind, may exist, though in very minute quantity, also as exciting causes of influenza, an idea suggested by Dr. Prout. It may possibly be of volcanic origin; and such a substance as seleniumated hydrogen, which, even in extremely minute quantity, is highly deleterious, might perhaps account for some of the phenomena of influenza; but we must acknowledge that nothing certain is known of exciting the cause of this disease. See Distemper, Epidemic, and Murrain.

INOCULATION. An operation in the management of fruit trees, which is sometimes called budding. It is a kind of grafting practised in the summer months on various trees and plants, and often succeeds better than the common method of grafting. (See Budding and Grafting.) It is also a term used to signify the process of transplanting grasses. See Grasses.

INSECTS (Lat. inset). A very extensive and the most important class of animals. Insects are distinguished from Worms by always having feet in their perfect or winged state, as the beetle, butterfly, moth, &c. Worms crawl on their bellies, and have no feet, as the earth-worm, snail, slug, &c. Insects, above all other animals, are by far the most destructive to vegetation.

On the subject of the science of entomology, in this work, we propose only to touch upon those which are the most injurious or important to the farmer; and many of these, such as the bee, ant, fly in turnips, wire-worm, &c., will be found under their respective heads; indeed the mere list of known insects is so numerous, that the catalogue alone would be too extensive for a work of this description. "The great characteristic of this vast assemblage of animals," says Mr. Swainson "is the total absence of internal bones; hence, their hardest parts are always external, and the muscles are usually attached to the under side of the substance which forms the covering of the animal. The body is always divided into rings or transverse joints, from which circumstance naturalists have agreed to call them annulose, or ringed animals." This name is peculiarly applicable, since it expresses a marked distinction from such as have an internal skeleton, analogous to that of man, and which are called Vertebrata, from possessing a spine. The Annulosa contain Insecta (insects proper); Arachnida (spiders); Crustacea (crabs); and Annelida (worms); excluding the soft Vermes of Linneus, which include the shell-fishes, or mollusks. So diversified, indeed, are the different groups of this immense assemblage, or sub-kingdom of the animal world, that it is impossible to assign to them any other character, as a whole, than that just mentioned.

From the works of Mr. Swainson, of Kirby and Spence, the papers of Mr. Duncan, in the Quart. Journ. of Agr., the work of V. Kollar, On Insects injurious to Gardener, Forrester, and Farmers, and especially from that of Dr. Harris, the chief facts are obtained. In the words of M. Kollar, "The real purpose of this book is intended, to find more easily the insect particularly interesting to each, it has been considered proper not to treat of families and species in any systematic arrangement, but according to the branch of culture to which they are particularly injurious." And, in pursuance of this object, I shall only briefly allude to some of the chief of the insect depre-
dators, for "to enumerate," says Davy, "all the destroying animals and tyrants of the vegetable kingdom, would be to give a catalogue of the greater number of the classes in zoology; almost every species of plant is the peculiar resting-place or dominion of some insect tribe; and from the locust, and caterpillar, to the minute aphid, a wonderful variety of inferior insects are nourished, and live by their ravages upon the vegetable world."

Of the considerable extent to which the various insect tribes commit their depredations, no farmer will for a moment doubt, and yet he forms his judgment only upon the ravages of the larger insects. Of the smaller tribes, the farmer will, perhaps, only discern the activity of the animals—those only discernable through the microscope, he forms no estimate. Yet of those that he does see, the catalogue is fearfully alarming.—"There is," says Mr. Duncan, "scarcely one
of our most useful plants which is not assailed in some way or other; and the forms of insects, and their modes of living, are so infinitely diversified as to enable them to continue their depredations in all the different states of these plants. The various kinds of grain, for example, have a host of enemies in the subterranean larva of beetles which consume the roots; various kinds of caterpillars feed on the blade; some particular species attack the ear; and even when laid up in apparent security, a small beetle is often found to scoop out the interior of each grain, and convert it into an abode for itself. (See Corn Weevil.)

In England, if the seed of the turnip escape the attack of a minute weevil, another enemy awaits the unfolding of the cotyledon leaves, and a third buries itself in the bulb and rootlets, which become diseased and covered with unseemly excrecesces (see Aneur), while the mature foliage is often consumed by caterpillars.

"But even when there is no remarkable augmentation of their numbers, there is reason to believe that the injury occasioned to vegetation by insects is at all times greater than is generally supposed. Their operations are often carried on under cover, either beneath the surface of the soil, within the substance of the plant, or in other situations where they escape observation. Many kinds again feed only during the night, and conceal themselves during the day in holes and crevices. In consequence of this latent and insidious mode of attack, there is no doubt that we are often led to ascribe the unhealthiness and decay of plants to badness of soil, unfavourable weather, and other causes, when in reality they are produced entirely by insects." (Quart. Journ. Agr. vol. viii. p. 97.) The only course," adds Mr. Duncan, "which is likely to lead to the discovery of proper remedies, is to investigate carefully the habits and natural history of insects in connection with the structure and general physiology of the plants on which they attack. In prosecuting this object, the attention should be directed to ascertain the time when, and the manner in which, the eggs are deposited, as well as their composition, and that of the enclosing membrane, with a view to determine in what way the vital principle might be most easily destroyed. The habits of the larvae call for particular attention, as it is generally in this state that the mischief is committed; the period of their appearance, their times of feeding, plants on which they feed, and (if attached to more than one) the kind they seem to prefer, the part of the plant attacked, duration of the larvae state, should be carefully noted; an acquaintance with the places to which the larvae usually retreat when about to change to pupa, and with the structure, duration, &c. of the latter, might probably suggest some easy means of destroying many in that dormant state. A knowledge of the economy of the perfect insect is of course of the utmost importance; if we could become acquainted with the retreats in which they pass the winter, or find means to destroy the few that generally survive, when they first appear in the spring, and before they have de-

POSTED THEIR EGGS, THE INJURIES WHICH ARE SUSTAINED BY THEIR MEANS MIGHT BE ALTOGETHER PREVENTED." (Ibid. p. 99.)

Let not, however, the farmer, when he is thus warmly engaging in the destruction of the annoying insects of the field, omit to consider whether many of these are not, in some shape or other, productive of benefit—whether they do not serve to keep within reasonable limits other insects, or perhaps perform some other wise purpose in the works of the creation. This has been proved to be the fact in the case of the common earth-worm, whose casts so often annoy the gardener and the farmer. (See Earth-Worm.) For these not only assist in the continual admixture of different strata of earths, but, by boring the soil, they promote in it the circulation of the atmospheric gases, and even the drainage from it of its superficial moisture. And as White, of Selborne, remarks in his Natural History, "The most insignificant insects and reptiles are of much more consequence, and have much more influence in the economy of nature, than the infernious are aware of. From their minuteness, which renders them less an object of attention, from their numbers and fecundity, earth-worms, though in appearance a small and despicable link in the chain of nature, yet, if lost, would make a lamentable chasm."

Insects have been divided by entomologists into two great divisions—the winged and the wingless.

Winged insects are divided into the following orders:

1. Coleoptera. Of this order are the weevils, the rose-bug, ground and dung beetles, &c.
2. Orthoptera. Of this order are the cockroach, field cricket, grasshopper, &c.
3. Hemiptera. Of which are the field, tree, and bed-bugs, fetid bugs, &c.
4. Neuroptera. In which are comprehended the dragon fly, lace fly, ephemeras, &c.
5. Hymenoptera. In this order are bees, wasps, ants, saw-flies, gall-flies, &c.
6. Lepidoptera. Of which are the butterflies, moths, &c.
7. Rhippipera. Of which are certain minute insect parasites living on bees, wasps, &c.
8. Diptera. Of this order are gnats, house flies, musketoes, ox and horse flies, &c.

The insects without wings (Aptera) are divided into the following orders:

9. Myriapoda. Of this are the centipede, Iulus, &c.
10. Thysanura. Including small, soft, leaping insects, generally covered with a silvery down, and found in damp places, under logs, &c.
11. Parasita. The lice tribe, &c.

I. The Transformation of Insects—Insects commonly change their form several times in the most apparently magic manner. A few, the Aphid, for instance, are viviparous, but they are generally produced from eggs, that is, the eggs are produced in the body of the mother. "The female," says Kollár, "lays her eggs (which are often stuck on and covered with a kind of glue to protect them from the weather) shortly after pairing, instantly in the place best adapted for their development,
and which offers the proper food to the forthcoming brood.

Most insects issue from their eggs as larvae; those of the butterflies are provided with feet, and are called caterpillars; those of beetles, grubs; and when they have no feet, they are called maggots. In this state, as their bodies increase, the insects often cast their skin, and sometimes change their colour. Many winged insects, such as the grasshoppers, dragon-flies, &c., very much resemble in their larva state the perfect insect; they only want the wings, which are not developed till after the last change of the skin. The larva state is the period of feeding; and insects are then usually the destructive enemies of other productions of nature, and objects of persecution to farmers, gardeners, and foresters.

The nymph or pupa state succeeds that of the larva. Insects do not now require nourishment (with the exception of grasshoppers and a few others), and repose in a death-like slumber. To be safe from their enemies and the weather, the larvae of many insects, particularly butterflies, prepare for themselves a covering of a silky or a cottony texture. Many form themselves a house of earth, moss, leaves, grass, or foliage. Many even go into the earth, or decayed wood, or conceal themselves under the bark of trees, and other places of security.

After a certain fixed period the perfect insect appears from the pupa. It is usually furnished, in this state, with other organs for the performance of its appointed functions, as for the propagation of its species, &c. The male insect seeks the female, and the female the place best suited for laying her eggs; hence most insects are furnished with wings. Food is now a secondary consideration; consequently, in many, the feeding organs are less perfectly developed than in the larva state, or very much modified, and suited for finer food, as, for example, in butterflies, which, instead of the leaves of plants, only consume the honey out of the flowers.

II. The food of insects is indeed procured from an extensive pasture. "From the majestic oak," observes M. V. Kollar, "to the invisible fungus or the insignificant wall-moss, the whole race of plants is a stupendous meal to which the insects sit down as guests. Even those plants which are highly poisonous and nauseating to other animals are not refused by them. But this is not yet all. The larger plant-consuming animals usually limit their attacks to leaves, seed, and stalks; but so insensible is the taste of the flowers of which every part of a plant yields suitable provender. Some which live under the earth, attack roots; others choose the stem and branches; a third division live on the leaves; a fourth prefers the flowers; while a fifth selects the fruit or seed. Even here a still further selection takes place. Of those which feed on the roots, stems, and branches, some species only eat the rind like the bee-hawk moth; others the inner bark and the albumen, like the bark beetle; a third divest the plant of the sap vessels, as the aphides; others devour the substance of the leaves without touching the epidermis, as the mining caterpillars; others only the upper or under surface of the leaves (leaf rollers), while a fourth division (as the larva of the Lepidoptera) devour the entire leaf.

Of those feeding on flowers, some eat the petals (the rose-bug, &c.), others the stamens (bees, &c.); a still greater number consume the honey from the nectaries (wasps, flies, &c.); other insects injure the plant by puncturing it, and laying their egg in the wound, and with it an acid matter, which causes a peculiar excrescence in which their young are hatched and live, until they are able to eat their way out, to perform the functions of the parents, such as the gall-fly, &c. The death-watch or ticking beetle (Anobium) feeds on dry wood, long used, as portions of our dwelling houses.

Those insects which tenant and feed upon animal matters, have an equally varied taste: of these are the different kinds of bird and sheep lice, &c., gnats, midges, breeze flies, bugs, fleas, &c. Some of the carnivorous beetles devour their prey entire; others only suck out their juices; others live upon the food they obtain in water, and devour swarms of the infusoria. Many live on carrion and the excrements of the larger animals, such as the dung-beetle, and carrass-beetle; others live in the stomachs of animals; many moths live entirely upon hair, leather, wool, and feathers.

The food of insects varies strangely with their transformations: the caterpillar requires very different food from the butterfly; the maggot from the beetle and fly. The larva of the Sirex gigas feeds on wood, the perfect insect on flies. Those of some melolonthians live on roots and tubers, the beetle on leaves. The quantity of food consumed by different insects varies very much: many consume more than their own weight in a day. The maggot of the fly and fly, according to Redi, consumes sometimes ten times heavier in the course of 24 hours. Caterpillars digest every day about one-third to one-fourth of their weight; hence the ravages they commit in a few days. Of others, however, such as the day-flies (Ephemeroidea) and the breeze-flies, and even amongst the Lepidoptera which spin cocoons, many appear to abstain from nourishment. Some eat only during the day, others in the evening; and others, such as the caterpillars of the night moths, during the night. Most of them provide their own food; but a few which live in communities, such as the wasps, bees, ants, &c., are fed by the perfect insect. Many provide a store of food, but the greater number die unprovided with a store: others feed their larva." See Beetle, and BORERS.

III. Destruction of Insects, &c. by Artificial Means.—Various have been the recipes suggested for the destruction of the insects which destroy the cultivator's crops. Ants, it is said, may be easily destroyed by toasting the beetle and feeding the ants with a piece of bacon; till it is crisp, and laying it at the root or stem of any fruit tree that is infested by these insects, placing something over the bacon to
INSECTS.

keep it dry—the ants will go under it; after a
time lift it up quickly, and dip it into a pail of
water. While treating of insects, I may inci-
dentally allude to worms and slugs, or naked
snails. For the destruction of slugs, warm in
an oven, or before the fire, a quantity of cab-
bage leaves, until they are soft, then rub them
with unsalted butter, or any kind of fresh drip-
ping, and lay them in the places infested by
slugs. In a few hours the leaves will be
found covered with slugs and slugs. Wood-
lice are destroyed in the same way. For field
operations, perhaps, the best means of destroy-
ing slugs and worms is common salt, an agent
too little known for this purpose, yet its powers
are undoubted.

No person has employed common salt for the
purpose of destroying worms to a greater extent
than Jacob Busk, Esq., of Ponsbourn Park,
Hertfordshire. His valuable experi-
ments have extended over some hundreds of
acres of wheat. To use his own words,—“In
every situation, and at every time, the effect
appeared equally beneficial.” The quantity
per acre,—“about four or five bushels sown
out of a common seed-shuttle.” The period.—
“In the evening.” The effect,—“In the morn-
ing each throw may be distinguished by the
quantity of slime and the number of dead slugs
lying on the ground. In some fields it has cer-
tainly been the means of preventing the de-
struction of the whole crop.” Six bushels of
salt per acre was applied by hand, in April,
1828, to a field of oats attacked by the slugs
and worms, and the crop was completely saved
by this application, although an adjoining field,
not salted, was entirely destroyed by this sort
of vermin.

Salt, too, is a complete preventive of the ravages of the weevil in grain. It has been
successfully employed in the proportion of a
pint of salt to a barrel of wheat. I learn from
an American merchant, that wheat placed in
old salt barrels is never attacked by these de-
structive insects. Six or eight pounds of salt
sprinkled over 100 sheaves in stacking, pro-
duces exactly the same effect.

The Erionota lanigera upon apple trees, and
several other insects (See American Blight),
may be killed by clay and water, made as thin
as whitewash, and mixing with every 6 gallons
of it 2 lbs. of cream of tartar, 1 lb. of soft soap,
and half a peck of quicklime. “When you
think,” says Mr. Loudon, “that the weather
is likely to continue dry for some time, take
a bucketful of this mixture, and with a large
brush wash over the bark of the trees, where-
ever you think it has been infected with the
bug. A man will dress a number of trees over
in a few days with a whitewash brush and this
liquid; it is only necessary to be careful to do
in dry weather, so that the rain may not
wash over the mixture for some time. The
clay and water alone are sometimes effectual.

Flies and wasps.—A mixture of pepper, sugar,
and water will speedily attract and destroy
vol. iii. p. 1071.)

Moss and Insects.—Mr. Thomas recommends
that the trees infected should be sprinkled
with a fine powder in March, and again in Oc-
tober, on a foggy day when the trees are damp
but not dripping, and I have no doubt of its
efficacy. It is composed as follows: slack five
bushels of lime, hot from the kiln, with com-
mon salt and water (say one lb. of salt to each
gallon of water). When the lime has fallen to
a fine powder, add by small quantities at a
time a bushel of soot, stirring it until com-
pletely incorporated. Mr. Thomas has found
that one man can dust over with the powder fifty
trees in a day, and that the moss in the turf
under fruit trees thus treated is also completely
destroyed by the application. (Trans. Soc. Arts.)

Worms in grass plats may be readily destroyed
by copiously watering the turf with lime-water
(half a pound of the hottest quick-lime well
stirred in each gallon of water), or by sprink-
ling common salt (20 bushels per acre) over it,
or by strewing it on gravel walks in rather
large proportions. Lime is recommended for
the destruction of the worm which sometimes
injures young larch plantations; coal-tar and
tar water to preserve hop polies and other
wood from the ravages of insects. The cater-
pillars on cabbages may be readily destroyed
by sprinkling them with finely powdered lime;
and when some years since a black caterpillar
attacked very generally and extensively the
turnips, in some instances they were very suc-
cessfully destroyed by turning into the fields
considerable numbers of common ducks. Heavy
rolling, especially during the night, is in many
cases destructive of slugs; and it is cer-
tain that, by occasional material variations
in the rotation of crops (see Rotation or
Crops), the number of predatory insects may be
very considerably reduced in cultivated
soils by depriving the larvae of their particular
and essential food.

Mr. knight recommends the use of carbonate
of ammonia for the destruction of the insects
upon the pine and other plants. Mr. Baldwin,
in effect, does the same, when he recommends
the use of the fresh or remitted horse
and dung. Mr. Robertson found soot (which con-
tains ammonia), when diffused in water, to be
an excellent application. When speaking of
the use of fermenting horse dung in the de-
struction of insects, Mr. Knight remarked,—“I
conclude the destructive agent in this case is
ammoniacal gas, which Sir Humphry Davy
informed me he had found to be instantly fatal
to every species of insect; and, if so, this
might be obtained at a small expense by pour-
ing a solution of crude muriate of ammonia
upon quicklime. On the same principle I can
afford an equally efficient, though less delicate
fluid. The ammoniacal gas might, I conceive,
be impelled by means of a pair of bellows
amongst the leaves of the infected plants, in
sufficient quantity to destroy animal without
injuring vegetable life.” Ammonia seems pe-
culiarily distasteful to insects. Carbonate of
ammonia is often successfully placed in meat-
safes to prevent the attacks of flies.

IV. The natural Enemies of Insects.—Amongst
the enemies by which insects are kept in
check, unless embayed long slumber, and
late frosts, inundations, storms; and, among
the animals, bats, mice, moles, squirrels, foxes,
&c. Birds devour them by myriads; the green-

3 x 2
665
INSECTS.

flinch tears open (says Reaumur) the strong nest of the yellow-tailed moth, and eats the infant caterpillars. The woodpeckers and tree-creepers commit great ravages amongst the beetles and caterpillars. Crows, which in some sections destroy the corn, commit great ravages upon cutworms and destructive insects. In one of the English counties where the rook (a bird allied to the crow) had increased so as to do some damage to the crops, a destructive war was waged against them, so that they were nearly exterminated. But under these circumstances various species of the insect tribe increased so rapidly, that it became necessary to import the rooks again from the adjoining counties. In fact it remains in fact proved whether any omnivorous bird is more prejudicial than useful. Insects in their various states exist throughout the warm season, whilst the crops are exposed to the birds for a comparatively short period. Every protection should be given to birds, and boxes should be fitted up for martins, wrens, and bluebirds. To these may be added the frog, the toad, &c. Many insects, such as the ground beetles, devour the pupae of others. Then, again, there is the numerous order of the Ichneumonidae, which lay their eggs in the bodies of other insects and destroy them. The eggs are hatched within the body of the living insect, and the young parasites, in the most literal sense, fasten on the entrails of their prey. At last the wounded caterpillar sinks, the enemies escape through the skin and become pupae; or the caterpillar, notwithstanding its internal parasites, enters the pupa state; but, instead of a butterfly, one or more Ichneumonidæ appear. The beautiful little red insect familiarly known as the lady-bird or lady-bug, is of vast service by the havoc which it makes among the plant and bark-lace. Many a friendly ichneumon fly or lady-bird has been killed by those whose want of knowledge led them to consider these insects destructive to vegetation. To these wonderful animals we often owe the preservation of our orchards, woods, and grain. Many other modes, besides those I have enumerated, have been suggested, by which the number of the cultivator's predatory insects may be reduced, most of which I shall notice under their respective heads. I am quite of the opinion, however, of the authors of the work I have so extensively quoted, "that the most essential and necessary means to be opposed to the serious injuries caused by insects, consists in the universal dissemination of the knowledge of the natural history of hurtful insects amongst farmers, gardeners, foresters, and all those, in fact, who are in any manner connected with agriculture."

V. Of the Insects which live and propagate on domestic animals. —The chief are lice, which commonly originate from want of cleanliness, poor, unwholesome food, or from the weakening effects of other diseases. Old horses are more subject to them than young ones; they are common in sheep, and in swine; for which the best remedies will be found under their respective heads. (For the bots in horses, see Bot; for those in sheep, see Sheep Bot; for the ox-warble, see Warble.) The forest fly, or horse fly, lives chiefly on horses. It flies in short flights quickly, and moves about with considerable agility. The female lays but one egg at a time, from which the fly is hatched. This abound in the New Forest. See Horse Fly.

The well-known sheep tick has no wings; the fore part of its body is very small, but the abdomen is large. Its colour reddish, with white lines on the side of the abdomen. The farmer will find the following an excellent receipt for a sheep-dipping wash, by which they are readily destroyed:—½ a lb. of powdered white arsenic, 4½ lbs. of soft soap. Boil these for a quarter of an hour, or until the arsenic is dissolved in the water. Add this to the water sufficient to dip fifty sheep. The quantity of arsenic usually recommended is too large. See Ticks.

VI. Insects which injure Bees. —There are several insects which injure bees, such as a parasite bee-louse, which is about the size of a flea, has no eyes, but the rudiments of four feelers. They tenant chiefly populous hives; sometimes two or three are found on a bee. These parasites disturb and annoy even the queen bee. "A bee," says M. Kölår, "infested with a bee-louse, (infesta) beto no purpose, to get rid of such an unwished-for guest, till at last she creeps under a number of other bees, and rubs off the louse from her back, when it immediately betakes itself to the back of another bee. That the presence of this parasite causes pain to the bee, is apparent from the restless manner with which she runs out at the hole and back again. The queen is also disturbed in her employment of egg-laying, when she is infested by them, so that the hive suffers in another way by impoverishment. It may even happen that when many of these parasites infest a queen, she must eventually perish. In winter the infested bees usually fall to the floor, and perish with cold and hunger." Spiders also destroy bees, but only in their nests. Then there is the caterpillar of the honeycomb-moth, whose rages are very considerable, when once they find their way into a hive. They devour the wax. Three hundred have been found in a hive, and there are two generations of these each year. Ants also are very fond of honey, and find their way into hives. Wasps very frequently do the same. Bees even rob each other's hives.

VII. The Insects which injure Grain. —These are numerous: the chief of them are the larvae which feed on the green leaves and roots of grain. On these the blackbirds, crows, and other useful birds feed very copiously. The barley-midge (Tiphula cerealis) attacks the barley and spelt plants.

VIII. Insects which injure Meadows. —This is also a very numerous class. "Most of the insects that choose the various sorts of corn for their food," says M. Kölår, "do not reject the other sorts of grasses, in the meadows. The herbage of the meadows has also often peculiar enemies, which are very difficult to find out and destroy. In most cases the meadows suffer from the roots of the grass plants being injured, which is chiefly occasioned by the larvae of various species of cockchaffers, living
DESTRUCTIVE INSECTS, &c.
Insects.  

In the earth. When bare spots are seen on meadows, we may be pretty sure that the larvae of some species of melolontha are there carrying on their work of destruction. The subterranean plough disturbs the operations of these vermin, and the cows devour them.

Insects injurious to cultivated Vegetables—Are also numerous, and highly injurious to the gardener’s crops. The flea-beetles (Halticina) are great pests to the gardener: they attack and devour, during the summer months, various members of the cabbage tribe, such as the cabbage, cauliflower, and colewort, the turnip, the radish, common and water cress: they also prey upon flax, hops, sainfoin, &c. (See Flies.) The mole cricket (Gryllotalpa) is often peculiarly injurious to the German cultivators. It does not confine its ravages to the garden crops, but injures very materially those of the meadow and corn-fields. It measures, when full-grown, about two inches in length. The plant-lace (Aphis) chieﬂy haunts the cabbage, pea, and beans. They are devoured in great numbers by several of the lady-birds (Coccinella) and fly tribes.

X. Insects which injure Green-house Plants.—Of these I need only mention the orange scale insect (Coccus hesperidum); the pine-apple scale insect (Coccus bronchela); the mealy bug (Coccus Anodidum); the oleander scale insect (Aephipitus acraptor), abounding on oleanders, acacias, aloes, palms, &c.; the rose scale (A. rose), found in old rose stems and twigs; the cactus scale (A. cicaeae), on the cactus; the sweet-bay scale (A. lauris), on the sweet bay; the rose-moth (Tinea (Ornia) rhodophaga); and the plant-mite or red spider (Aecnus telarius).

XI. Insects which attack Fruit Trees.—The number of insects which live either partially or entirely upon fruit trees, is very considerable. I can hardly do more in this work than give the names of the most formidable of these injurious pests.

XII. Insects injurious to Forest Trees.—These are divided by M. Kollár into two classes:—1. Those which attack deciduous trees; and, 2. Those which are injurious to the evergreens.

XIII. Insects which attack the Fir and Pine Tribe—These often injure very seriously the leaves, bark, and young shoots of some of the Pinus tribe.

Such, then, is a very brief glance at that immense and important class of animals which are included in the science of entomology. It must be considered, to use the words of Mr. Swainson, only as suggestions and stimulants to further inquiry. The review, however, cannot but fill us with astonishment; for, although we see only a very limited portion of the insect world, yet that view, limited as it is, is fraught with instruction to the cultivator. It will lead him, perhaps, to a clearer understanding of the often-repeated truth, that nothing is created in vain. It may suggest to him also the means, in some cases, of arresting their ravages, when, by their numbers, they become a nuisance; and it may perhaps be instrumental in saving from destruction many a useful bird, when the sportsman is made aware of the number of predatory insects which they so unceasingly destroy. The astonishing number, habits, and instincts of the insect tribe, too, are equally instructive, and can only be explained in one way. These phenomena did not escape the notice of the great Paley. Thus he observes, “Moths and butterflies deposit their eggs in the precise substance (that of a cabbage, for instance) which, if not the butterfly herself, but the caterpillar which is to issue from her eggs, draws its appropriate food. The butterfly cannot taste the cabbage; cabbage is no food for her; yet in the cabbage, not by chance, but studiously and electively, she lays her eggs.” And when referring to this immense mass of animal life, he says, in another place, “To this great variety in organized life the Deity has given, or perhaps there arises out of it, a corresponding variety of animal appetites. For the final cause of this we have not far to seek. Did all animals covet the same element, retreat, or food, it is evident how much fewer could be supplied and accommodated than what at present live conveniently together, and find a plentiful subsistence. What one nature rejects, another delights in. Food which is nauseous to one tribe of animals, becomes, by that very property which makes it nauseous, an alluring dainty to another tribe. Carrion is a treat to dogs, ravens, vultures, fish. The exhalations of corrupted substances attract flies by crowds. Maggots revel in purifaction.” Neither can the astonishing changes of some of the insect tribe be regarded by a rational being without very considerable interest. “The wonderful metamorphosis undergone by the order Lepidoptera,” says Swainson, “would be almost incredible, were it not familiarized to us from early childhood, that a crawling worm, ravenous of grass food, should voluntarily seek a retreat in the earth, or spin its own shroud; that such a change should come over it, so complete, as that not a lineament of its first form was retained; that in this state, after retaining its form of a chrysalis, if it should remain inanimate, it should suddenly burst forth, full of life and joy, and, with many-coloured wings, ascend into mid-air, and derive its only sustenance from the nectar of flowers;—all this, we say, is one of those miracles of nature, which, were it told of an insect that had never yet been seen, the world would not believe.”

Description of the Plate of Noxious Insects.—Throughout this work we have made great use of the valuable treatise of Dr. Harris on destructive insects; but, as it is unaccompanied by plates, the reader who is unacquainted with the subject may be occasionally in doubt as to the aspect of those described. On this account we have devoted Plate 16 to the illustration of a few of the principal forms, both of destructive insects and those which prey upon them. The species figured are,

1. Elaphidion putator, oak pruner. See Boers, p. 205.
2. Clytus ficerosus, locust tree boier. See Boers, p. 206.
5. Phyllographa quadricata, p. 175, 173.
—6. Hylobius pales, which is very destructive to the pine forests of the south. The plum
weevil and grain weevil, as well as this species, belong to the Curculio family.
7. Agrotis clandestina, cut-worm.
8. Ageria exitiosa, peach tree borer, female.
10. Carassus Goryi, which may be taken as a representative of a large family which feeds upon other insects, caterpillars, etc.
11. Coccinella borealis, which in its larva and perfect state, feeds upon the aphides so destructive to roses and other plants.

INSTEP. In farriery, a name given to that part of a horse's hind-leg which reaches from the ham to the pastern joint.

INSURANCE. One means of security against fire. The farmer being constantly surrounded by much combustible matter, should never, when possible, omit rendering himself safe by insuring his stock of every kind in some public office, instituted for this purpose.

In England, the legislature has wisely afforded very considerable facilities to the insurance of farming stock, which, by an act of Parliament, is exempted from duty. “The Farmer's Insurance Institution” of London insures it at 1s. 9d. per cent., without the average clause; thus easily repaired are the ravages of the incendiary, of accidental fires, and lightning.

INTEGUMENT. The outer covering or skin of an animal: it is also used in the same sense as a synonyme for Testa, for the husk or exterior covering of seeds.

INVENTORY (Fr. inventaire; Lat. inventarium). A detailed account taken of any thing upon a farm. Inventories of the various kinds of farming stock should be taken annually, at the close of the year. See Book-keeping and Appraisement.

INVolUCRE, or INVolUCRUM. In botany, the bracte (or small leaves placed near the calyx, or the peduncle or pedicill) which surround the flowers or the umbels. Involute: are the parted involucres of unumbelliferous plants. (Paxton's Bot. Diet.)

IRIS (from iris, the rainbow; alluding to the variety and beauty of the colours of the flower). This extensive genus has long been, as it still continues to be, a great favourite in the flower garden. "The sword-leaved sorts (says Sweet) do best in a light loamy soil, and increase freely by suckers from the roots or by seeds. The tuberos-rooted ones are more difficult to cultivate, and thrive best in a mixture of loam, peat, and sand, as does also the tribe to which I. perviscus belongs, as I. alata, I. canescens, I. reticulata, &c. The common bulbous species do well in any garden soil, the more sandy the better." I. tuberosa is aromatic as well as emetic and purgative, and I. versicolor and I. tenua are used in the United States as cathartics. (Paxton's Bot. Diet.) Two species of iris only are indigenous to England,

1. The yellow water iris, or flower-de-luce (I. pseud-scorne), which grows wild in ditches, pools, and rivers, and forms a handsome ornamental for the banks of ponds and streams, blowing from three to six large, bright yellow flowers in July. The root is horizontal, depressed, brown, very astringent; the stem 3 or 4 feet high; leaves erect, ribbed, grass-green. The disks of the larger segments of the flowers are pencilled with dark purple.
2. Stinking iris, or Gladwyn. Roast-beef plant (I. fatidissima). This species grows in groves, thickets, and under hedges, but it is rather rare. Dr. Withering, however, observed it to be very common in England in all the southwest counties. It is a perennial, growing to about 2 feet high; the leaves are dull green, exhalung, when rubbed, a scent compared to that of roast beef, to which it is no compliment. The flowers, which appear in May, are dull, pale purple, pencilled with dark veins. Seeds orange-coloured, polished. (Eng. Flor. vol. i. p. 48.)

Miller only mentions 19 species of cultivated irises, but there are now nearly 100 known species and varieties. Two or three only are much admired as ornamental flowers. The I. xiphium is a bulb from Spain, blowing blue, white, yellow, and violet flowers in June. The Persian iris blows a fragrant flower in March and April; plant the bulb in October, in a pot filled with equal quantities of fine mould and sand, and house it during frost. The dwarf iris is ornamental in clusters in a garden; it grows only three inches high, and blows in April. Part its roots in autumn. The Siberian iris blows in June, and likes a moist situation; it bears flowers whose falling petals are blue, and the upright ones dark purple; its stem is tall, and its leaves are narrow. I. susana, or fleur-de-lis. The plant is tuberous rooted, loves a good soil, and should be removed every three years. It flowers handsomely in June, bearing varieties of pale blue, deep blue, and striped or bluish-white flowers. Its odour is feeble, but it is fetid. These are the most favourite kinds in gardens. The I. florentina, which is occasionally seen in our gardens, yields the orris root, which is the dried and peeled rhizomes of the plants. Orris root is prized chiefly on account of its colour, which resembles that of the violet. It is added on this account to tooth powders and hair powder. A hazardous custom prevails of giving the entire root to infants to gnaw during teething, from which fatal results have followed.

The wild flag, Colour-changing flax (Iris Virginina), is common on the margins of ponds and in miry places in the Middle States. Dr. Bigelow remarks that the root of this is a violent emetic. Seven or eight other species of iris are enumerated in the United States. (Flor. Centr.)

IRON-WOOD (Carpinus ostrya). See HORN-BEAM.

IRRIGATION (Lat. irrigo, to water). In agriculture, the watering of the earth, to increase its productiveness. The term, however, is confined to that species of flooding which consists of spreading a sheet of water over a field or meadow, in such a manner that it can be easily withdrawn.

Irrigation, or the artificial watering of the
IRRIGATION.

earth, chiefly to produce increased crops of grass, has been in use from a very early period. In Oriental countries, in fact, the heat of the climate is such, that in many situations the now productive soil would be absolutely sterile, were it not that the cultivator enriched his ground with a copious supply of water. The simile employed by Isaiah (i. 30: 24) to indicate barrenness and desolation, is "a garden that hath no water." And that, in patriarchal times, they laboured hard to supply their grounds with water by means of various hydraulic machines, some of which resembled the water-wheels of the fen districts of England, and were worked by the feet of men, something after the style of the modern treadmill, is certain. Moses alluded to this practice when he reminded the Israelites of their sowing their corn in Egypt, and watering it with their feet (Dont. xi. 10; 2 Kings, xix. 24), and in the sandy soils of Arabia the same system is still compounded (Niebuhr, vol. i. p. 121.) According to Dr. Shaw, the following is the modern mode of raising and using the water of the Nile for the purpose of irrigation in Egypt. "Such vegetable productions as require more moisture than what is occasioned by the annual inundation of the Nile, are refreshed by water that is drawn at certain times out of the river, and lodged in large cisterns made for that purpose. The screw of Archimedes seems to have been the instrument formerly made use of for that purpose, though at present the inhabitants either supply themselves with various kinds of leathern buckets, or else with a sakiah, as they call the Persian wheel, which is the most useful and generally employed machine. Engines and contrivances of both these kinds are placed all along the banks of the Nile, from the sea to the cataracts, their situations being higher, and consequently the difficulty of raising the water being greater, as we advance up the river. When their pulse, saffron, melon, sugar-canes, &c. (all of which are commonly planted in it), have been refreshed, they take out a plug from the bottom of the cistern, and then the water gushing out, is conducted from one rill to another by the gardener, who is always ready as occasion requires to stop and divert the current. In Egypt at the present day, according to Dr. Clarke, the water is sometimes raised for the purposes of irrigation by means of a wicker basket lined with leather, which is held by cords between two men, who, by this laborious means, swing it over the banks of the Nile into the canal which is planted in it, the lands intended to be irrigated. A machine similar to the Persian wheel is still employed in China by the cultivators for the purposes of irrigation. This use of machinery for the purposes of watering might, in fact, in many situations, be advantageously employed in England to a much greater extent than is commonly believed. It is well known how many thousand acres of valuable land are profitably drained by means of the steam-engine. At this very period a public company is proposing to enclose the marshes of Lincolnshire, by the assistance of its gigantic aid. Yet how rarely, if ever, is that power employed to irrigate the thirsty lands of England; lands of all others the most profitable, the best adapted for the formation of water meadows. The tracts to which I allude are those on a slope, as on the side of a hill; but these are rarely found in situations where a sufficiently copious supply of water can be constantly obtained for the purposes of irrigation. Yet the quantity thus required is not so large as to be beyond the power of the steam-engine to supply; thus, to sufficiently saturate a square yard of a calcareous sand soil with water to the depth of one foot, as in irrigation, requires about 30 gallons of water, equal to about 145,000 gallons per imperial acre. Now, that the steam-engine could readily and profitably supply this quantity of water may be concluded from several facts; thus, the two engines, one of 80, the other of 60 horses' power, which keep Deeping Pen, near Spalding, completely drained, when working, in 1835, only 96 days, of 12 hours each, raised more than 14,000,000 tons of water several feet. The district drained by them contains about 25,000 acres (Brit. Farm. Mag. N. S. vol. iii. p. 300), which would otherwise be a complete swamp. And it has been proved that, by a common condensing steam-engine, one bushel of coals will raise more than 50,000,000 lbs. of water one foot. In many situations, therefore, where, for the purposes of irrigation, good river water can be successfully obtained, and fuel is at a moderate price, I am confident that great results are yet to be obtained by the aid of mechanical power. For, by the steam-engine, the soils of all others the best adapted for irrigation, may be successfully brought into cultivation; for instance, the poor sands and gravels on the sloping banks of many of the English and Scottish rivers, many of whose waters, from being charged with organic matter, the carbonate and sulphate of lime, and various earthy substances, are excellent for the use of water meadows. The early employment of irrigation by the Egyptians and Chinese was most likely the result of the good effects which were observed to be produced by the overflows of the Nile and the Chinese rivers; for, in the "Celestial Empire," irrigation has, it seems, been employed, according to their veracious historians, for a period long before that assigned to the flood. In Italy, especially on the banks of the Po, the cultivators of the earth have certainly employed this process for a period previous to the days of Virgil (Georg. lib. i. v. 106—9).—

Deinde satia fluvium induct, rivosque sequentes

and it is still carried on with a zeal and care worthy of the art they practise. M. P. Cato, the earliest of the Roman writers upon agriculture (150 years before Christ), in his ninth chapter, told the Italian farmers to "make water meadows, if you have water, and if you have no water, have dry meadows." The directions of Columella seem to have all the freshness of a modern age about them. He was the first who noticed the inferior nutrition afforded by the hay from water meadows. "Land," says he, "that is naturally rich, and is in good heart, does not need to have water set over it; and it is better hay
IRRIGATION.

which nature, of its own accord, produces in a juicy soil, than what water draws from a soil that is overflowed. This, however, is a necessary practice when the poverty of the soil requires it; and a meadow may be formed either upon a stuff or free soil, though poor when water may be set over it; neither a low field with hollows, nor a field broken with steep rising ground, are proper; the first, because it contains too long the water collected in the hollows; the last, because it makes the water run too quickly over it. A field, however, that has a moderate descent may be made a meadow, whether it be rich, or so situated as to be watered; but the best situation is where the surface is smooth, and the descent so gentle as to prevent either showers, or the rivers that overflow it, remaining too long; and, on the other hand, to allow the water that comes over it quietly to glide off; therefore, if in any part of the field intended for a meadow, a pool of water should stand, it must be let off by drains, for the loss is equal either from too much water, or from too little. (N. H., lib. vii. c. 14.) Pliny tells us that “meadows ought to be watered immediately after the spring equinox, and the waters restrained whenever the grass shoots up into stalk.” (Nat. Hist. lib. xviii. c. 27.) When, after the fall of the Roman Empire, agriculture, in common with all other sciences, rapidly declined, a very remarkable exception to this melancholy result of slavery and despotism was presented in the case of irrigation, which was carried on and extended through the long period of the dark ages with equal richness and success. This was more especially the case in Lombardy, where it was certainly prosecuted on a very bold and profitable scale long before 1037. The princes of Lombardy patronised and followed the example of the various religious establishments which then monopolized all the wealth and learning of the land, in extending the employment of water in all possible directions. The monks of Chiaizeville, in particular, were so celebrated for their knowledge of this branch of agriculture, and of hydraulics in general, that the emperor Frederick the First, in the last century, very gladly sought their advice and assistance. This system has ever been zealously and carefully extended and improved in every possible way. The waters of the chief rivers of the north of Italy, such as the Po, the Adige, the Tagliamento, and of all the minor streams, are employed in irrigation. There is no other country, which possesses an extent of rich water meadows equal to that of the Lombards. The entire country from Venice to Turin may be said to be formed into one great water meadow: yet the irrigating system is not confined to grass lands; the water is conveyed into the hollows between the ridges in corn lands, into the low lands where rice is cultivated, and around the roots of vines. From Italy the practice extended into the south of France, into Spain, and then into Britain. In the States of Lombardy, the water of all the rivers belongs to the state; in those of Venice, the government extends its claims to that of the smallest springs, and even to collections of rain water; so highly, for the use of the cul-
tivator, is water of every kind valued in the north of Italy. It is necessary, therefore, in Lombardy, to purchase from the state the water taken from the river; this may be taken, by means of a canal, through any person’s grounds, the government merely requiring the payment of the value of the land to the proprietor, and restraining him from carrying his channel through a garden, or within a certain distance of a mansion. The water is sold by the government at a certain rate, which is regulated by the size of the sluices, and that time the run of water is used; this is either by the hour, half-hour, or quarter, or by so many days at certain periods of the year; the right to these runs of water is regularly sold like other property. Arthur Young gives an account of the sale of an hour’s run of water through a sluice near Turin, which produced, in 1778, 1500 livres. The rent of the irrigated lands in the north of Italy is, upon an average, more than one-third greater than the same description of land not watered. (Com. Board of Agr. vol. ii. p. 189.)

In Bengal, wells are dug in the highest part of their fields, and from this, by means of bullocks and a rope over a pulley, water is raised in buckets, and conveyed in little channels to every part of the field. No attempts at cultivation are here made without the assistance of water, obtained by some mode or other. (See India, Agriculture of.) The art of irrigation was not confined to the Old World. The Mexicans practised it long before the days of Columbus; they collected the mountain torrents, and conducted their waters to their fields in proper channels, with much care and address. It was only towards the termination of the 17th century that water meadows were constructed in Britain upon any thing like a regular system. Of these, those in Wiltshire, which are amongst the most celebrated in England, especially those in the Wyley Bourn, were made between 1700 and 1705. Those of Hampshire and Berkshire were constructed about the same period, but they were at first formed very inferior to the modern noble water meadow lands of those countries. Great improvements were made towards the conclusion of the 18th century, through the publications of G. Boswell on Meadow Watering in 1780, and of the Rev. T. Wright, of Auld, in Northamptonshire, whose writings appeared at intervals from 1789 to 1810. It is noticeable that the water employed for these celebrated southern meads is perhaps the most clear and swift flowing of all the English rivers; issuing from the chalk formation, it is equally copious and transparent. Some of the chief advantages, therefore, of irrigation may evidently be derived from almost any description of water; for it is proved by the good effects produced by the brilliant chalk waters of the south of England, and the still greater fertilizing effect of those surcharged with organic matter, as in the Craigintinny meadows, near Edinburgh, that there is no water too bright, or too full of impurities, to be useless for the purposes of irrigation.

I propose, in this paper, to investigate the chemical properties of river water, and of the
IRRIGATION.

Effects produced by it in irrigation, adding a few remarks upon the practice of the best and most skilful cultivators of the water meadows of the south of England.

1. With regard to the composition of river water, there have been several chemical examinations; that of the Thames was analysed by Dr. Bostock, who found, in 10,000 parts, after most of its mechanically-suspended matters had subsided, about 1/3 parts of foreign substances, viz.:

<table>

</tr>
<tr>
<td>Muriate of soda</td>
<td>0-02</td>
</tr>
</tbody>
</table>

In an equal quantity of the waters of the Clyde, Dr. Thompson found 1/5 part of solid substances, namely:

</tr>
<tr>
<td>Silica</td>
<td>0-115</td>
</tr>
</tbody>
</table>

The water of the Ichen, in Hampshire, is one of the most celebrated of all the southern streams, for the use of the irrigator. I found, in 10,000 parts of water, about 2/3 parts of solid matter, viz.:

<table>
<thead>
<tr>
<th>Organic matter</th>

</tbody>
</table>

From an examination of the substances found in these streams (and they afford a pretty correct view of the contents of most others), the farmer will see that they all yield ingredients which are the food or natural constituents of the grasses. Thus, sulphate and carbonate of lime are found in most of them, and there is no river-water which does not contain, in some proportion or other, organic matter. To ascertain, therefore, whether pure water was alone able to effect all the magic effects of irrigation, it was necessary to employ other water than that of rivers, lakes, or even springs. Pure water, as obtained by distillation, therefore, has been tried as a supporter of vegetation, but it was found totally inadequate to the support of plants; they merely vegetated for a time, but they could not, by any means, be made to perfect their seeds. In this conclusion the experiments of Dr. Thomson, and of MM. Saussure and Hassenrattz, entirely agree. Pure water, therefore, notwithstanding the dreams of the Greek philosophers, and the celebrated deceptive experiments of Van Helmont with his willow tree, is not able to support the growth of the grasses. Van Helmont's tree, when he planted it in an earthen pot, weighed 5 pounds; the earth, previously dried in an oven, weighed 200 pounds; after 5 years it weighed 164 lbs., although it had been watered during that time with only rain and distilled water, and the earth had lost only two ounces of weight. Hence, said Van Helmont and his disciples, water is the sole food of plants. Bergman, in 1773, first pointed out the source of error. He showed, from the experiments of Margraff, that the rain-water contained a sufficient quantity of earth to account for the increased weight in the willow, every pint of rain-water containing one grain of earth. Then, again, the earthen vessel (which was sunk in the earth) would, in this experiment, transmit its moisture imregnated with all kinds of soluble substances. And yet it is shown by the analysis of pure water, such as that from a sewer, or from a dunghill, is alone sufficient to sustain vegetation. This was clearly evidenced in the experiments of M. Lampionius; for he found that plants placed in a pure earth, such as silica or alumina, although they would not grow when watered with pure water only, yet, when watered with the liquid drainage of a dunghill, they flourished very luxuriantly, and this fact has been also proved in another way. It has been shown, by chemical analysis, that the quantity of solid or earthy matters absorbed by plants is in exact proportion to the impurity of the water with which they are nourished. Thus, equal quantities of some plants of beans, fed by distilled water, yielded—

These facts strongly confirm the conclusions of some of the most sagacious cultivators, that the chief advantages of irrigation are attributable to the foreign substances with which the water is charged; although, as I have elsewhere observed, almost every farmer has a mode of accounting for the highly fertilizing effects of irrigation; one thinks it cools the land, another, that it keeps the grass warm in winter. And this was Davy's opinion. He thought that a winter flooding protected the grass from the injurious effects of frost. He says, "Water is of greater specific gravity at 42° than at 32°, the freezing point; and hence, in a meadow irrigated in winter, the water immediately in contact with the grass is rarely below 40°, a degree of temperature not at all prejudicial to the living organs of plants. In 1804, in the month of March, I examined the temperature in a water-meadow near Hungerford in Berkshire, by a very delicate thermometer. The temperature of the air at 7 in the morning was 43°. In general, those waters which breed the best fish are the best fitted for watering meadows; but most of the benefits of irrigation may be derived from any kind of water."

Such were the opinions of Davy as to the fertilizing properties of water. It is to be regretted that the opportunities for agricultural observations of this great chemical philosopher were so few, for his valuable remarks were always cautiously made. He appears, however, as I have remarked elsewhere, never to have steadily investigated the chemical composition of river-water, with regard to its uses in irrigation, and, in consequence, knew little of the value of some of its impurities to vegetation. Thus, if the river-water contains gypsum (sulphate of lime), which it certainly does if the water is hard, it must, under ordinary circumstances, on this account alone be highly fertilizing to meadows, since all grasses contain this salt in very sensible proportions; for, calculating that one part of sulphate of lime is contained in every two thousand parts of river-

671
IRRIGATION.

water, and that every square yard of dry meadow soil absorbs only eight gallons of water (and this is a very moderate allowance, for many soils will absorb three or four times that quantity), then it will be found that, by every flooding, more than one hundred weight and a half of gypsum per acre is diffused through the soil in the water, a quantity equal to that generally adopted by those who spread gypsum on their clover crofts, lucern, and saintoin, as a manure, either in the state of powder, or as it exists in ashes. And if we apply the same calculation to the organic substances ever more or less contained in flood-waters, and allow only twenty parts of animal and vegetable remains to be present in a thousand parts of river-water, then we shall find, taking the same data, that every soaking with such water will add to the meadow nearly two tons per acre of animal and vegetable matters, which, allowing, in the case of water-meadows, five floodings per annum, is equal to a yearly application of one ton of organic substances. The quantity of foreign substances present in river-water, although commonly less, yet very often exceeds what I have thus calculated to exist in it. I have found it impossible, however, to give, from analysis, the amount which, under ordinary circumstances, is present in river-waters, with any tolerable accuracy, since the proportion not only varies at different seasons of the year, but a considerable proportion of the merely mechanically suspended matters subsides, when the specimens water is suffered to rest. In my conclusions with regard to the theory of irrigation, I have found many excellent practical farmers concur. Thus, Mr. Simons, of St. Croix, near Winchester, considers that the great benefit of winter flooding for meadows is derived, in the first place, from the deposits made by the muddy waters on the grass; and, secondly, from the winter covering with water preventing the ill effects to the grass of sudden transitions in the temperature of the atmosphere. This gentleman is perfectly aware of the value of the addition of the city drainage of Winchester to the fertility of the Itchen river-water, and of its superiority for irrigation after it has flowed past the city, having water-meadows both above and below the town; and he finds that, if the water has been once used for irrigation, that then its fertilizing properties are so materially reduced, that it is of little value for again passing over the meadows; and so convinced is he of this fact by long experience, that, having in this way long enjoyed the exclusive and valuable use of a branch of the waters of the Itchen for some grass land, a neighbour higher up the stream followed his example, constructing some water-meadows, and using the water before it arrived at those of my informant, who, in consequence, found the water so deteriorated in quality (though not sensibly diminished in quantity), that he had once thought of disputing the right with his more upland neighbour. The experience of other irrigators tends to the same conclusion. In the best-managed water-meadows of Hampshire, the farmer does not procure annually more than three crops of grass; yet in situations where a richer water is employed, as near Edinburgh, four or five are readily obtained. It is evident, therefore, that the chemical properties of water have a much greater influence in irrigation than is commonly believed. The quality of the water, therefore, employed for the purposes of irrigation, is of the first importance to be well understood by the farmer; and although many more modern discussions have taken place upon the subject, yet the definition which the great Lord Bacon gave, in his Natural History, of the advantages of "Meadow Watering," has never been excelled—"that it acts not only by supplying useful moisture to the grass, but likewise by carrying nourishment dissolved in the water." This nourishment is, generally speaking, composed almost entirely of the animal and vegetable matters mechanically suspended or chemically dissolved in the water; the fouler the water, the more fertilizing are its effects. The objection which has been sometimes urged to this explanation, by instances where the water was very shallow and the objects of some of the muddy waters (as those of the Humber) on meadow lands, is very erroneous; for, in those cases, the mud deposited on the grass did not consist of animal or vegetable matters, but of fine earthly particles, such as clay or chalk, substances of which the alluvial soil, on which the same flood waters had for ages occasionally deposited their earths, was in fact entirely composed, and to which, in consequence, any further supply was almost useless, the earthly slime merely covering the grass with mud, without adding a single fertilizing ingredient not already abounding in the soil. If, however, the soil is naturally deficient in any of the earthly ingredients contained in the water, then even such flood waters are ever found most fertilizing.

"The agency of water in the process of vegetation," says Dr. Stephens, "has not till of late been distinctly perceived. Dr. Hales has shown that, in the summer months, a sunflower, weighing three pounds avoirdupois, and regularly watered with very clear water, in 22 ounces each day, that is, half its weight. Dr. Woodward found that, in the space of 77 days, a plant of common spear-mint increased 17 grains in weight, and yet had no other food than pure rain water; but then he found that it increased more in weight when it lived in spring water, and still more when its food was Thames water." (Practical Irrigator, p. 2.) And when speaking of the fact, that some irrigators think clear spring water equal to any, he adds (p. 24), "I would recommend to those who are of the same opinion, to inspect the irrigated meadows which are watered by the washings of the city of Edinburgh, where, I trust, they will find the superiority of muddy water to that of clear spring water most strikingly manifested."

Edinburgh has many advantages over the most of her sister cities; the large supply of excellent spring water is one of the greatest blessings to her numerous inhabitants, both in respect to household purposes and keeping the streets clean, as well as irrigating the extensive meadows situated below the town, by the rich stuff which it carries along in a state of semi-
IRRIGATION.

solution, where the art of man, with the common sewer water, has made land hillocks produce riches far superior to any thing of the kind in the kingdom, or in any other country.

By this water, about two hundred acres of grass land, for the most part laid into catchwork meadows, are irrigated; whereof 130 belong to W. H. Miller, Esq., of Craigintinny, and the remainder to the Earls of Haddington and Moray, and other proprietors. The meadows belonging to these noblemen, and part of the Craigintinny meadows, are what is called the old meadows, containing about 50 acres, have been irrigated for nearly a century. They are by far the most valuable, on account of the long and continual accumulation of the rich sediment left by the water; indeed the water is so very rich, that the tenants of the meadows lying nearest the town have found it advisable to carry the common sewer water through deep ponds, into which the water deposits part of the superfluous manure before it runs over the ground. Although the formation of these meadows is irregular, and the management very imperfect, the effects of the water are astonishing; they produce crops of grass not to be equalled, being cut from four to six times a year, and the grass given green to milk cows.

The grass is let every year, by public sale, in small patches of a quarter of an acre and upwards, and generally brings from 24 l. to 30 l. per acre per annum. In 1826, part of the Earl of Moray's meadow fetched 57 l. per acre per annum.

About 40 acres of the Craigintinny lands were formed into catch-work meadow before the year 1800, which comprises what is called Pilkiside Bank old meadows, and is generally let at from 20 l. to 30 l. per acre per annum. In the spring of 1821, 30 acres of waste land, called the Freegaft Whins, and 10 acres of poor sandy soil, were levelled and formed into irrigated meadow, at an expense of 1000 l. The pasture of the Freegaft Whins was let, previously to this improvement, for 40 l. per annum, and the 10 acres for 60 l. They now bring from 15 l. to 20 l. per acre per annum, but may be much improved by judiciously laying out 200 l. more in better leveling that part next the sea, and carrying a larger supply of water to it, which might be easily done without prejudice to the other meadows.

This, perhaps, is one of the most beneficial agricultural improvements ever undertaken; for the whole of the Freegaft Whins is composed of nothing but sand, deposited from time to time by the action of the waves of the sea. Never was 1000 l. more happily spent in agriculture; it not only required a common sewer to bring about this great change, but a resolution in the proprietor to launch out his capital on an experiment upon a soil of such a nature. Since the making of the Freegaft Whins into water meadows, Mr. Miller has levelled and formed 40 acres more of his arable land into irrigated meadow, worth, before the formation, 9 l. per acre per annum. It will only require a few years before these meadows will be as productive as the former; for it is evident that the longer water is suffered to run over the surface of grass land, the greater quantity of fertilizing substance will be collected; therefore, as the water is so very superior in quality to all other water, a speedy return for the capital laid out may be expected. The expense of keeping these meadows in repair is from 10 s. to 15 s. per acre per annum, which is more than double the expense of keeping water meadows in repair in general.

It by no means, however, follows, as a necessary result of any contemplated improvement in irrigation, that the water should previously undergo a chemical examination. There are many other modes by which the farmer can form a pretty correct conclusion as to the fertilizing properties of the water he proposes to employ.

"The surest proofs," says Mr. Exeter, "of the good quality of water (and the observations of this gentleman will be readily confirmed by the irrigators of the southern counties) as a manure, are the verdure of the margin of its streams, and the growth of strong cresses in the stream itself; and wherever these appearances are found, though the water be perfectly transparent, the occupier of the soil through which it flows may depend, in general, on having a treasure, if he is attentive to it; but that this is not invariably the case, and that there are instances where a good water will not improve the herbage of certain soils, is proved by the following account (and there are several other cases with which I am acquainted) of the meadows of Mr. Orchard, of Stokes Abbey, Devon. These two meadows are situated on the side of a hill, their aspect nearly south—the superstratum a fine rich loam, from 8 to 10 inches deep, on a substratum of strong yellow clay. No difference whatever can be seen by the naked eye, in either the upper mould or the substratum, or in the herbage growing on the surface of them; except that, in the lower part of one, a few rushes appear, in consequence of some small springs which rise near them, but the water from them is not sufficient to render any part of the land poachy. At the head of the two meadows is a large pond, formed by the collecting of some small runs of spring water rising near it, and which is also improved by the wash of a small farm-yard adjoinging, which, of course, must add to its efficacy as a manure. When this water is thrown over one of the meadows, it produces the richest herbage in abundance, and this field is regularly mowed for hay; on the other meadow, though repeatedly tried, it produces no good whatever." (Ann. of Agr. vol. xxx. p. 206.)

This result is attributable to the superior tenacious, retentive quality of the substratum of the lower field, or of some chemical difference in the composition of the soil; and although almost any description of soil is adapted to the formation of water meadows, those of a heavy or clayey description are generally the most unsuitable, those of a light or peaty kind are better, and those with a sandy or very absorbent gravel substratum still more so. There are some of the most celebrated water meadows on the banks of the Kennet of this de
IRRIGATION.

scrip tion, and many of the best on the banks of the Wiltshire Avon have a mass of broken, porous flints for a subsoil. Those near Edin-

It is evident, therefore, that it is as important an object in the construction of these meadows to secure a ready and rapid exit for the water as to procure, in the first instance, a copious and fertilizing supply.

The farmer is generally well aware of the injurious effects on his meadows of suffering the water to remain too long on them. He watches, therefore, with much care, for the first indications of fermentation having commenced, which is evinced by the rising of a moss or scum to the surface of the water—puf- 

tration is now beginning in the turf, and he knows very well that if the water is not speedily removed, that his grass will be either materially injured, or entirely destroyed; he hastens, therefore, to open his water-courses.

There are some soils in the vicinity of Stanen, in Berkshire, however, of so porous a quality, that they need not any drains to empty the water-courses; and, in fact, in many instances, the farmer does not even require them: after a few hours all the water is absorbed by the soil; and yet these lands, with hardly 6 inches of mould above the gravel, are amongst the richest of water-meadows; the roots of the grasses penetrate readily into the gravel, and the earliest and sweetest grasses are produced on them.

Almost any description of grass will flourish under proper management in water-meadows. Those whose soils consist of peat resting on sand, or on sandy loam, with a substratum of chalk or gravel, generally produce the meadow foxtail (Alopecurus pratensis), the brome-grass (Bromus arvensis), and the meadow-fescue (Festuca pratensis), on the tops and sides of the ridges. The furrows and sides of the drains are usually tenanted by the creeping-bent, the hard-fescue, the rough-stalked meadow-grass, and the woolly soft-grass. In those water-meadows whose soil consists of a sandy loam on a clay subsoil, the chief grasses are commonly the creeping-rooted soil-grass, the crested dog's-tail, the meadow barley, and the sweet-scented vernal-grass. But some grasses change their appearance in a very remarkable degree, when exposed under favourable circumstances to the influence of the flood-waters. This fact is strikingly exemplified in the case of two small meadows situated at Orchester, six miles from Amesbury, in Wilts- 
shire, denominated, from their great produce, "the long grass meads." These, says Davis, "contain together only two acres and a half, and the crop they produce is so immense, that the tithe hay of them was once sold for 5 guineas." Much discussion took place amongst the Wiltshire farmers as to the nature of the crop of these meads, before it was at last shown that the greatest part of their herbage consisted of nothing else than the black-couch, or couchy-bent, the Agrostis stolonifera, one of the worst of the grasses or weeds which haunt the poor ill-cultivated arable soils.

It is a very general, as well as correct con- clusion of the English farmers, that the grass and hay of water-meadows is not so nutritious as that of the permanent pasture lands. The difference, however, is not great, as is commonly supposed. The late Mr. George Sinclair determined this experimentally, and he is no mean authority with regard to all that relates to the grasses.

He obtained from the rye-grass (Lolium per- 

renne), at the time of flowering, taken from a water-meadow that had been fed off with sheep till the end of April, of nutritive matter 72 grains; and from the same weight of this grass, taken from a rich old pasture, which had been shut up for hay about the same time, 92 grains. From the same grass from the meadow, that had not been depastured in the spring, 100 grains. And from the same grass from the pasture which had not been fed off, 120 grains. All the grasses, in fact, where their growth is forced by the application of either liquid or solid manures, are found to contain nutritive matter in diminished quantities: this, too, was determined by Sinclair. From 4 ounces of a very rankly luxuriant patch of rye-grass, on which a large portion of cow-dung had been deposited, he obtained of nutritive matter 72 grains. From the same quantity of the same grass growing on the soil which surrounded this luxuriant patch, he obtained 122 grains.

And, in a second trial, the same species of grass, on a soil entirely destitute of manure, afforded of nutritive matter, 95 grains. On the same soil, excessively manured, the grass afforded only 50 grains. In these experiments the plants were of the same age, and were ex- 

amed at the same stage of their growth. (Hortus Gram. 384.)

With regard to the construction and manage- 

ment of water-meadows, there are many practical works of the highest authority to which the farmer has ready access; and, in the following observations, therefore, I shall merely very briefly paraphrase the accounts given by Mr. Davis and others, of the practice of irrigation in the southern counties. In this, however, even since the time that Davis wrote, there has been a great and steady improvement. The land is better levelled, the slopes more evenly preserved, the water-way, aqueducts, and hatches, better constructed, and in many of the more recent improvements, in the valley of the Itchen, in Hampshire, the sliding-water doors are regulated by a cogged wheel turned with a movable winch, so as to render them safe from alteration during the absence of the meadow-keeper.

The management of the Wiltshire and Hampshire water-meadows, as well as it can be briefly described, is as follows:—In the au- 

The management of the Wiltshire and Hampshire water-meadows, as well as it can be briefly described, is as follows:—In the au- sumn the after-grass is eaten off quite bare, when the manager of the mead (provincially the droumer) begins to clean out the main drain, and the main carriage, and to "right up the works," that is, to make good all the car- riages and drains which the cattle have trod- den in, so as to have one tier or pitch of work ready for drowning. This is immediately put under water, whilst the droumer is preparing the next pitch.
In the flowing meadows this work ought to be done, if possible, early enough in the autumn to have the whole meadow ready to catch the first floods after Michaelmas; the water, being the first washing of the arable lands on the sides of the chalk hills, as well as the dust from roads, is then thick and good; and this remark, as to the superior richness of the flood waters, is one that is commonly made in Berkshire and other parts of England. The length of the autumnal watering cannot be precisely stated, as much depends upon situations and circumstances; but if water can be commanded in abundance, the custom is to give meadows a “thorough good soaking at first,” perhaps for a fortnight or three weeks, with an intermission of two or three days during that period, and continue for the space of two fortnights, allowing an interval of a week between them. The works are then made as dry as possible, to encourage the growth of the grass. This first soaking is to make the land sink and place the grass together, and as a consequence, not only to the quantity, but to the quality of the grass, and particularly to encourage the shooting of new roots, which the grass is continually forming, to support the forced growth above.

While the grass grows freely, a fresh watering is not wanted; but as soon as it flags, the water must be repeated for a few days at a time, always keeping this fundamental rule in view, “to make the meadows as dry as possible after every watering, and to take off the water the moment any scum appears upon the land, which shows that it has already had water enough.”

Some meadows that require the water for three weeks in October, and the two following months, will not, perhaps, bear it one week in February or March, and sometimes scarcely two days in April and May.

In the catch-meadows, which are watered by springs, the great object is to keep the works very dry between the intervals of watering; and as such situations are seldom affected by floods, and generally have too little water, it is necessary to make the most of the water, by catching and rousing it as often as possible; and as the upper works of every pitch will be liable to get more water than those lower down, a longer time should be given to the latter, so as to make them as equal as possible.

Davis’s Agriculture of Wiltshire, p. 125–127.)

In Berkshire they first flood their water-meadows about Michaelmas; these are situated principally on the banks of the Kennet. The first flooding they deem the richest in quality: they keep on the land for about four days, and they then dry them for about a fortnight, and after that the water is let on for three or four days more: those meadows which are the most readily dried are the most productive. There are none more so, in fact, than those which have a porous, gravelly, or broken flint bottoms, from which the flood-water readily escapes, almost without drains. They begin to feed their meadows with sheep about the 6th of April, and continue feeding till about the 21st of May, when the meadows are again flooded for a crop of hay; the land is then flooded and dried alternately for three days until hay-time.

The number of acres of land in Wiltshire, under this kind of management, has been computed, and with a tolerable degree of accuracy, to be between 15,000 and 20,000. Some considerable additions, however, have been made to the water-meadows of the district since this calculation was made. (Davis’s Wilt’s., p. 129.)

About the same number of acres are formed into water-meadows in Berkshire, and a still larger number in Hampshire. No one has attended more carefully to his water-meadows than Lord Western, on some of those situated on the London clay-formation in the Black-water valley, in Essex, a soil of all others, perhaps, from its tenacity, the least adapted to their successful formation, and his testimony is very important:—“There is an old adage,” says his lordship, “that water is the best servant in agriculture, and the worst master. Water has in itself intrinsic value; distilled through soil or sand, or marsh, it acquires by absorption of their qualities, though preserving the most perfect transparency, and, coming down in torrents and floods, it carries along the finer particles of earth and manure from the mountains, or higher grounds, into the valleys; hence, of course, it is that the valleys derive their fertility, and the value of the meadow has been originally created by an accumulation of wealth from the hills.”

In descending the Jura mountains, which divide France from Switzerland, the very first pasture you find on the descent embraces the value placed on the mountain floods by the inhabitants of those districts; and, accordingly, every stream is sedulously directed and conducted over the pastures in a most skilful manner. The very washing of the roads in hasty rains is also attended to and applied to the same purposes.” This system of catching the uncertain flood-waters is known amongst farmers by the name of catch-work, and though highly valuable, yet they deem it infinitely less important to them than irrigation, which is watering generally five or six times a year) from a certain and ever-accessible head of water, as a river, &c. And yet Lord Western’s testimony is decisive in favour of even one catch-flooding; for he observes, when speaking of the expense of constructing the requisite little channels to disperse the flood-waters over the grass, “In many cases it will be trifling, in some cases considerable; but when the farmer reflects that one winter’s flooding will do more in many, I may say in most cases, than thirty loads an acre of the best rotten dung manure that can be laid upon his grass lands, he can hardly shrink from some considerable expenditure.” If, then, the effects even of a catch-flooding with water are so great, how infinitely superior are the advantages capable of being derived from a regular constant supply of the enriching foul waters, like those issuing from the drains of a large city, which is even now most successfully employed near Edinburgh, but worse than wasted in the case of London! Whatever may be the value, in an agricultural point of view, of the solid contents of the London sewers, yet to me the absolutely liquid
portions, for the purposes of irrigation, appear at least equally important.

Liebig informs us that, "in the vicinity of Liegen (a town in Nassau), from three to five perfect crops are obtained from one meadow, and this is effected by covering the fields with river water, which is conducted over the meadow, in spring, by numerous small canals. This is found to be of such advantage, that supposing a meadow not so treated to yield 1000 lbs. of hay, then from one thus watered 4500 pounds are produced. In respect to the cultivation of meadows, the country around Liegen is considered to be the best in all Germany."

There is no agricultural question, therefore, of more consequence, in a national point of view, than that of the improvement of the soil by the practice of irrigation; for, in its prosecution, all the rich, organic, and other matters diffused through the rivers, which would otherwise be carried into the sea, are saved to agriculture. This is not, therefore, a question like that attending most other modes of fertilizing the soil, merely transposing manure from one field or district to another; but it is the absolute recovery, as it were, from the ocean, of a mass of finely divided, enriching substances, constantly draining from the land. It is the effectual diversion of a stream which is ever steadily impoverishing all cultivated soils, and which unnoticed, and in too many instances deemed worthless, gliding into the ocean, is almost the only drawback to the steadily increasing fertility of our country.

IRRITABILITY OF PLANTS. See Botany, Temperature, and Acclimatization of Plants.

ISNARDIA (named in memory of Anthony Isnard, member of the Academy of Sciences). These plants are mere weeds, or creeping aquatic herbs, growing in marshy situations. The marsh isnardia (I. palustris) is the only indigenous species.

It is an annual, growing in ponds and watery places, blowing axillary, solitary, sessile, small, green, and inconspicuous flowers in July. The herb is floating, smooth, with numerous long filamentous roots. The stems are several, about a span long, simple, or slightly branched, leafy, bluntly quadrangular. The leaves are opposite, stalked, ovate, acute, entire, scarcely an inch in length, bright green, somewhat succulent, the mid-rib often red or purplish. (Eng. Flur. vol. iv. p. 264.)

The I. Palustris is common to America as well as to Europe, and is found from Canada to the West Indies. In Pennsylvania another species is met with—the Alternate-leaved Isnardia (I. alternifolia), commonly called Bastard Loose-stripe. The roots of both species are perennial.

Besides these, there are about a dozen additional species, as the genus is now constituted, in the United States. (Flor. Cestresia.)

ITALIAN RYE-GRASS. See Rye-Grass.

ITCH. In farriery, a cutaneous disease. See MANGE.

IVY (Hedera helix). The name appears to be derived from hedr, a Celtic word signifying a cord; and the English name ivy is derived from iv, a word in the same language signifying green.) A hardy evergreen climber, common everywhere in Europe, which is excellent as a screen planted against trellis-work. The common ivy is very often employed for covering naked buildings or trees, which latter it invariably kills. The stem is branched, either trailing on the ground and bearing 5-lobed white-veined leaves, but no flowers; or climbing, flattened and attached by dense tufted fibres, which serve for support, not nourishment; the flowering branches are loosely spreading, round, bearing ovate, undivided leaves. Umbels aggregate, green, many-flowered, their stalks covered with starry pubescence, and accompanied at the base by several small bracteas. The berry is the size of a currant, smooth, black, internally whitish and mealy, with seldom more than five seeds. The whole plant is somewhat aromatic; and a very fragrant resin exudes from the old stems when bruised.

IVY, AMERICAN, Virginia Creeper (Ameloposis heteraceus). Ivy-like ameloposis. The stem of this climbing plant sometimes grows 30 or 40 feet long, branching diffusely, climbing fences, trees, and walls, and clinging to them by adhesive expansions at the points of the tendrils. The leaves are digitate in clusters of fives, on long stems. The plant is common in the United States in woodlands, fence-rows, thickets, &c. Sir J. E. Smith (in Rees Cyclops,) contends that this is a true vites; but Dr. Darlington thinks, that although nearly allied to, it may be very properly separated from our grape vines. Two or three other species of ameloposis are enumerated in the United States.

IVY, GROUND. See Alehoop.

IVY, IRISH (Cauanesis), is a fast-growing climber, with large lobed leaves, which soon covers walls and houses. It is propagated by layers, or slips taken off and planted where they are to grow.

J.

JACOB'S LADDER, Blue or Greek Valerian (Polemonium caeruleum). This plant is a common ornament of flower borders in rustic gardens, of no particular qualities, notwithstanding its name of valerian, derived perhaps from the leaves, which resemble those of some of the Valeriana. The root is fibrous, not creeping, herb nearly smooth, perennial, 1/2 or
JOHN'S ARTICHOKE.

JOHN'S WORT. or ST. JOHN'S WORT (Hypericum). The generic name is said to be derived from *hypéros*, and *éikon*, an image. The superior part of the flower represents a figure. The common name is derived from their coming into flower about St. John the Baptist's day. The most part of the species of this extensive genus are showy plants. The greenhouse and frame shrubby kinds do well in loam and peat, and young cuttings root freely in sand under a glass. The hardy shrubs are well fitted for the front of shrubberies, being dwarf and showy. They may be increased by divisions or seeds, as well as the herbaceous kinds, which thrive well in any common soil. The seeds of the annual species have only to be sown in the open ground in the spring. Some of the species indigenous to Britain are as follows:

1. Large-flowered St. John's Wort (H. calycinum). A shrub, growing wild in bushy places in the west of Ireland and Scotland. The root of this species is creeping, the stems shrubby, erect, 12 or 18 inches high, with simple, leafy, square branches, smooth like every other part. The flowers, which appear from July to September, are 2 to 3 inches wide, of a bright golden yellow, with innumerable reddish tremulous anthers. This plant is a great ornament to shrubberies and parks, and excellent as a shelter for game, bearing any cold of our climate.

2. Tutsan, or Park Leaves (H. adnoseum). This shrub is found in moist, shady lanes, thickets, and woods in Britain and Ireland, but not very general. It is rather taller and more branched than the preceding. The flowers, which appear in July and August, are an inch wide, yellow, with three sets of stamens, and as many styles. The leaves and other parts have an aromatic scent when rubbed.

3. Square St. John's Wort, or St. Peter's Wort (H. quadrangularis). This species is perennial, and common in moist meadows and thickets, and about the banks of rivers. The root is somewhat woody, creeping; the herb smooth, light green; stems several, from one to two feet high, erect, leafy, acutely quadrangular; leaves elliptical or ovate, obtuse, many-rimbed, veiny, full of minute, colourless, pellucid dots, and bordered with a more or less perfect row of dark-coloured ones yielding a blood-red liquor. The uppermost branches form a leafy dense panicle of numerous lemon-coloured red flowers, about half the size of the last-described species.

4. Common perforated St. John's Wort (H. perforatum). This perennial species is met with abundantly in thickets, woods, hedges, and on dry banks. The root is woody, tufted, and somewhat creeping; the stem reaches to the height of 18 inches, and is round and bushy in consequence of the much greater length of its axillary leafy branches. The whole herb is moreover of a darker green, with a more powerful scent when rubbed, staining the fingers with a dark purple, from the greater abundance of coloured essential oil lodged in the herbage and even in the petals: the leaves are very numerous, smaller than the last, elliptical or ovate, obtuse, various in width; the flowers are numerous, in dense, forked, terminal panicles, bright yellow, dotted and streaked with black or dark purple. This species is eaten by cattle, and sheep, but is refused by horses and hogs. As this plant was found to bleed at the slightest touch, it was supposed to have a vulnerary quality, and became the “balm of the warrior's wound,” giving a blood-red colour to every composition, whether of a spirituous or oily nature, into which it entered. It contains resin, and the leaves give a good red dye to wool and oil.

5. Imperforate St. John's Wort (H. dubium). This species inhabits rather mountainous groves and thickets. The young radical shoots are bright red; the stem quadrangular in the upper parts, but not winged or bordered; the petals and calyx are dotted and blotched with dark purple.

6. Trailing St. John's Wort (H. hudsonianum). This is a pretty little procumbent smooth species, with the lemon-like scent of *H. dubium* and *perforatum*, which tenants sandy or gravelly, heathy, and rather boggy pastures. The root is fibrous, stem compressed, prostrate; flowers few, somewhat cymose; leaves elliptical, smooth.

7. Mountain St. John's Wort (H. montanum). Though not an ostentatious plant, this species well deserves John Banjin's epithet of "most elegant." The glutinous dark fringes of its calyx and bracteas resemble the glands of a moss-rose; the stems are erect, round, smooth, about two feet high; the leaves ovate, naked, clasping the stem.

8. Bearded St. John's Wort (H. barbatum), which grows for the most part in bushy places in Scotland, on an herbaceous stem a foot or more in height, flowering in September and October: 9. Hairy St. John's Wort (H. hirsutum), flourishing in thickets and hedges, chiefly on a dry, chalky soil, stem two feet high: 10. Small upright St. John's Wort (H. pulchrum), met with very frequently in woods and bushy, heathy places, on a clay soil; stem 12 to 18 inches high: 11. Marsh St. John's Wort (H. elodes), stems procumbent, creeping. There are other species, which call for no detailed description.

The whole genus, says Mr. Nuttall, in his account of the American species, appears to possess active medicinal properties in common with *visnaga*, which affords indeed much more abundantly a yellow and resinous gum, acting as a cathartic in doses of 7 or 8 grains. The *Visnaga guttata* of Surinam produces a kind of gamboge. 25 or 26 American species of *hypericum* are enumerated by botanists. The following are mentioned by Dr. Darlington as found in Chester county, Pennsylvania.
1. Hypericum Virginicum, or Virginia hypericum, having a perennial root, stem 18 inches to 2 feet high, whole plant of a pulshful hue, flowering in July and August, the blossoms being of a dull orange colour. It is found in wet, low ground, though rare.

2. H. punctatum, or dotted hypericum, frequent in open woodlands and fields, flowers of a pale yellow colour, with numerous oblong black dots, appearing in July and August.

3. H. perforatum, or perforated hypericum, commonly called St. John's Wort. This plant has a perennial root and stem growing from 1 to 3 feet high. It is frequent in fields and pastures where it puts forth its rich clusters of yellow, or orange-yellow flowers, from June to October. This, says Dr. Darlington, is an introduced and pernicious weed. The plant has a resinous odour; and is believed to produce troublesome sores on horses and horned cattle, especially those which have white feet and noses, the skin of such being more tender, or irritable. The dew which collects on the plant appears to become acidic; as I have seen the backs of white cows covered with sores, wherever the bushy ends of their tails had been applied, after dragging through the St. John's Wort. A tincture of the flowers and leaves has been used, it is said, with good effect in some complaints of the stomach and bowels.

4. H. quinquefolium, or five-nerved hypericum. This is frequent in low grounds, along streams. Its root is supposed to be annual, and its slender stems grow 6 to 12 inches high; the flowers have very small petals of a yellow colour.

5. H. Canadense, or Canadian hypericum. This so much resembles the last mentioned species as to be regarded by some botanists as identical.

6. H. sarothra, broom-like hypericum, commonly called ground pine, netweed, and orange grass. This is frequent in sandy fields and along roads and rails, with puts forth yellow flowers in July and August. Its root is annual, the stem is slender and grows 4 to 8 inches high. (Flora Cestrica.)

JONQUIL. A species of daffodil, of which there are several sorts. The great jonquil and the odorous jonquil blow about the middle of March. The lesser or proper jonquil somewhat later. When they blow well and early they forebode a fine season.

JUDAS TREE (Cercis). This is a beautiful genus of ornamental trees, flowering early in spring, and looking very pretty planted singly on a lawn, or trained to a wall or trellis; they grow to the height of 20 feet, prefer an open loamy soil, and may be plentifully increased from seeds.

The species found in the United States is the Cercis Canadensis of botanists, commonly called red bud. In the Middle States, it is a small tree 15, 20, or 30 feet high, greatly admired for the clusters of small flowers, which in April clothe the limbs in purple before the leaves appear. The flowers are acid to the taste. It is the emblem of exercise on the United States.

JUNE BERRY (Myrsine arbores of Michaux). With the exception of the maritime parts of the Carolinas and Georgia, this tree, as Michaux informs us, is spread over the whole extent of the United States and Canada. But it is most multiplied upon the Alleghany mountains, and upon the elevated banks of the rivers which flow from them. In the northern section of the Union it is called wild pear tree, whilst in the Middle States it is either Shad-tree, or various names of wild service berry, June berry, snowy medlar, and shad-flower. The last name is derived from its blooming about the time the shad ascend the rivers (beginning of April), when it is quite a showy little tree. The flowers, which are white and pretty large, are arranged in pannicles at the extremities of the branches. As it blossoms early, so does it mature its fruit among the earliest trees of the forest. The largest tree, however, rarely yields more than half a pound. Long culture has been found to improve the fruit, both in size and quality. The berries are roundish, 3 or 4 lines in diameter, smooth, dark-red, and even purple when mature, pleasant flavoured, and not unwholesome. In Pennsylvania and the neighbouring states, it is generally found in moist and shady situations, especially along brooks and rivulets. In the western country, however, it grows in the midst of the forest among the oaks, walnuts, &c., and here reaches its greatest height, which does not exceed 30 or 40 feet, with a diameter of 10 or 12 inches.

JUNIPER (Juniperus, derived from the Celtic juniperus, rough or rude, in allusion to the stiff habit of the shrubs). This genus is too well known to need to be particularized here. All the species will grow in sandy loam, and some in any common garden soil. They are mostly raised from seed, though cuttings will strike when planted in a sheltered situation, under a hand-glass. The stimulating and diuretic powers of the savin (J. sabina) are well known. The fruit of J. communis is proverbial for the flavour they give to gin. (Parthenus.) The species are all evergreen aromatic shrubs, with narrow leaves, either spreading and sharp-pointed, or closely imbricated, minute, and obtuse. The fruit is globular or oval, black or brown, with a glaucous efflorescence.

J. sabina is a native of the south of Europe, but it is cultivated as an evergreen in our gardens. The plant is a pyramidal shrub, with small, closely-adhering, glandular leaves, which exhale, when rubbed, a strong, heavy odour, and have a bitter, nauseous taste. By distillation they yield a large quantity of volatile oil, which has the odour and taste of the recent plant. Savin is a powerful acid poison, irritating and vesicating the skin when it is applied to it. When swallowed in large doses, it causes vomiting, purging, and inflammation of the stomach and bowels.

The common juniper (J. communis) grows wild on hills and heathy downs, especially where the soil is chalky. Dr. Sibthorpe found it on Olympus and Athe, in Greece. It is, like all the species, a bushy shrub, with evergreen, linear pointed, glabrous leaves, dark green on the under side. The flowers are axillary, small, sessile, male and female organs in separate flowers. The fruit, although called
JURY.
a berry, is a *galbanus* or succulent cone. It requires two seasons to arrive at maturity. The dwarf alpine juniper (*J. nana*) is a variety of the *communis*. It grows upon lofty mountains, and is, as its name implies, more humble in its growth. These are the only indigenous species. The tops and the fruit are used in medicine as powerful diuretics. The former have a bitter, turpentine flavour and colour; the fruit is sweetish, with an agreeable, somewhat balsamic odour, depending upon a volatile oil, and a peculiar saccharine matter analogous to the sugar of the grape. The volatile oil is contained in cells in the shells of the seeds; hence, in making infusion of juniper, the seeds should be bruised. The infusion is made with an ounce of the bruised fruit and a pint of boiling distilled water. It is a useful beverage in some kinds of dropsies. The red cedar (*J. Virginiana*), is a hardy, handsome evergreen, native of North America, with dark foliage, producing a small blue berry-like fruit in May. It frequently attains to the height of a very lofty tree. See *CEDAR*, RED.

KALE, SEA.

KALE, SEA (*Crambe maritima*), is found wild on the seashore on the southwestern coast of Great Britain, where the common people have from time immemorial been in the practice of watching when the shoots and leaf-stalks begin to push up the sand and gravel, in March and April, when they cut them off under ground, as done with asparagus, and boil them as greens. About the middle of the last century it was first introduced into gardens, and is now almost as universal as asparagus.

A light, moderately rich soil, on a dry sub-stratum, suits it best; though in any dry soil it will succeed. A bed may be composed for it of one-half drift sand, one-third rich loam, and one-third small gravel, road stuff, or coal ashes; if the loam is poor, a little well-rotted dung or decayed leaves being added. The soil must especially be deep, so that the roots can penetrate without being immersed in water, which invariably causes their decay. Mr. T. Barton, of Bothwell Castle, has even found it succeed well on a pretty strong loam that had a loose bottom. The depth should not be less than 2½ feet; and if not naturally deep, it should be worked to it by trenching. If at all tenacious, this opportunity may be taken to mix with it drift or sea sand, so as to reduce it to a mouldy texture. If the soil be wet it must be drained, so that water never shall stand within three feet of the surface. If poor, well-putrified dung must be added; but decayed leaves are preferable (*Trans. Hort. Soc. Lond.*, vol. i. p. 17), and sea-weed still more so. These precautions must all be particularly attended to, for upon the due richness and dryness of the soil not only depend the luxuriance and delicate flavour of the plants, but their very existence. Common salt, as might be anticipated, is found to be a very beneficial application, either applied dry, or by occasional waterings with a solution containing 4 or 5 ounces in the gallon, round every stool during the summer. As regards the situation, it cannot be too open or free from trees. Sea kale is propagated both from seed and slips of the root; the first is by far the best mode, for although it may be obtained from slips with greater certainty, yet the plants arising from seed are the strongest and longest lived; whilst the failure of seed, which is sometimes complained of, mostly arises from its being old, buried too deep, or some other extraneous cause. The seed may be inserted in drills from October, or as early in the spring as the ground can be brought into good condition. It is by much the best mode to leave the plants where raised, and with that intent, to guard against failure, inserting the seed in patches of 6 or 12 seeds, each 6 inches apart, and the patches 2 feet asunder. If, however, they are intended for transplanting, the seed may be sown in drills 12 inches asunder; in either case it must not be buried more than 2 inches below the surface; and it is a good practice, previous to inserting it, to bruise the outer coat of the seed, without injuring its vegetating power, as by this treatment the ger
mination is accelerated. The plants will in general make their appearance in 4 or 5 months, not sooner than 6 weeks; but, on the other hand, the seed will sometimes remain 12 months before it vegetates.

The best time for increasing it by slips is in March and April. Rooted offsets may be detached from established plants; or their roots, which have attained the thickness of the third finger, be cut into lengths, each having at least two eyes. To plant the offsets requires no particular direction: the cuttings must be inserted in an upright position 2 or 3 inches beneath the surface. It is best to plant two together, to obviate the danger of failure, at 2 feet apart, to remain.

Whatever mode of propagation is adopted, the bed should be laid out 3 feet wide, and a 2 feet alley between every 2, in preference to the plan sometimes recommended of planting 3 rows in beds 7 feet wide, for in such the soil must be consolidated by the feet during the necessary grades of cultivation.

If the months of June and July prove dry, the beds should be plentifully watered. The seedlings require no other attention during the first summer than to be kept free from weeds, and, if they come up too numerous, to be thinned to 5 or 6 in each patch. When their leaves have decayed, and been cleared away about November, they must be earthed over an inch or two with dry mould from the alleys, and over this about 6 inches depth of long litter be spread, and thus left to stand the winter. In the following spring the litter is to be raked off, and a little of the most rotten dung into the alleys. When the plants have perfectly made their appearance, they must be thinned, leaving the strongest plant, or, as Mr. Maher recommends, the three strongest, at each patch; those removed being transplanted at similar distances if required; but it must be remarked that those transplanted never attain so fine a growth, or are so long-lived. In this second winter the earthing must be increased to 5 or 6 inches deep over the crowns, and the covering of litter performed as before. In the third spring, the litter being removed, and some dung into the alleys as before, about an inch depth of drift sand or coal ashes must be spread regularly over the surface. The sprouts may now be bleached and cut for use; for if this is commenced earlier, the stools are rendered much less productive, and much shorter lived. In November, or as soon as the leaves are decayed, the beds being cleared of them, the coating of sand or ashes removed, and gently stirred with the asparagus fork, they must be covered with a mixture of three parts earth from the alleys, and one part of thoroughly decayed leaves, to the depth of 3 or 4 inches. The major part of this is to be removed in the following spring, the beds forked, and the covering of sand renewed; this routine of cultivation continuing during the existence of the beds.

The above course is the one also pursued if the plants are raised from offsets or cuttings, as it is much the best practice not to commence cutting until they are two years old. Blanching, as before observed, may commence the second spring after sowing. The most simple mode is that original, namely, to cover over each stool sand or ashes to the depth of about a foot; the shoots in their passage through it, being excluded from the light, are effectually bleached. But pots are by much to be preferred to these coverings. Common flower-pots of large dimensions may be employed, care being taken to stop the hole at the bottom with a piece of tile and clay, so as to exclude every ray of light.

Previous to covering the stools with the pots, &c., the manure laid in an enlarged bed must be removed; and the operation should commence at the close of February, or at least a month before the shoots usually appear, as the shelter of the pots assists materially in bringing them forward. In 4 or 6 weeks after they are covered the plants should be examined, and as soon as they appear 3 or 4 inches high, they may be cut; for if none are taken until they attain a fuller growth, the crop comes in too much at once. In order to prolong the season of production, Mr. Barton recommends plants to be raised annually, so that every year a cutting may be had from a yearling crop, which comes in much later, and consequently succeeds in production the old established roots. The shoots should be cut whilst young and crisp, not exceeding 5 or 6 inches in height; the section to be made just within the ground, but not so as to injure the crown of the root. Slipping off the stalks is said to be preferable to cutting. The plants may be gathered from until the flower begins to form, when all covering must be removed. If, when arrived at the state in which broccoli is usually cut, the stalks and immature flowers are employed as that vegetable, they will be found an excellent substitute; and this greatly enhances the value of the plant, as broccoli does not stand the winter frosts in the Northern States, and can only be had when carefully protected; but this plant is sufficiently hardy to bear the frost without injury. It flowers about June, and produces abundance of seed on every stem, which ripens about the close of July or early in August.

To force sea kale, Mr. F. Baldwin, of Hayle, recommends that, on each side of a 3 foot bed, a trench is to be dug 2 feet deep, the side of it next the bed being perpendicular, but the outer side sloping, so as to make it 18 inches wide at the bottom, but 2 1/2 feet at the top. These trenches being filled with fermenting dung, which of course may be renewed if ever found necessary, and frames put over the plants, the light is to be completely excluded by boards, matting, &c. Unlike the generality of vegetables, the shoots of forced sea kale are always more crisp and delicate than those produced naturally.

"To have this rare vegetable in perfection," says Bridgeman, "it should be cooked as soon as gathered. Let it be first soaked in water, seasoned with salt, for half an hour; then wash it in fresh water, and put it into the cooking utensil; keep it boiling briskly, skim clean, and let off steam. When the stalks are tender, which may be expected in from 15 to-
KALE.

25 minutes, according to size and age, take it up, dish it, and serve it up with melted butter, gravy, and such condiments as may be most agreeable to the palate." (Gardener's Assistant.)

KALE, THE WOBURN PERENNIAL. See CABBAGE, BORCHOLE, &c.

KALII. A sea weed, from the ashes of which the alkali, called soda, is procured. See KELP, SALTWORT, and GLASSWORT.

KALMA. American laurel. A North American genus of hardy shrubs, remarkable for the beauty of their flowers. The leaves are considered poisonous to cattle, and are particularly fatal to sheep. The honey gathered from the flowers is also charged with possessing deleterious qualities. The plants do best when grown in a peat soil, though they will grow in a very sandy loam; they may be increased by layers or seeds.

Mr. Nuttall describes five species of kalmia found in the United States: — 1. *K. latifolia,* laurel, or candy bush, common from Georgia to Georgia. The stem grows 3 or 4 to 10 or 12 feet high, with irregular, crooked, straggling branches. It frequents shaded banks and rocky hills, and blooms its beautiful flowers in May and June. The wood of this splendid flowering shrub is very hard, and is often used to make handles for small mechanical implements. A decoction of the leaves is sometimes used as a remedy for cutaneous diseases. (Flora Ceutrica.)

2. *K. angustifolia,* or narrow-leaved laurel, commonly called sheep laurel, and dwarf laurel. The stem is to the mode adopted by the Isle of Thanet and Suffolk farmers, of collecting the sea-weed for sheep, and suffering it to putrefy, is decidedly wrong; for, by being thus decomposed, half its fertilizing virtues are lost to the soil. The common excuse for rendering dung putrid before it is spread, viz. that it is a necessary practice to kill the seeds of weeds, has no application here, for those of marine weeds will not grow on arable upland soils.

The use of sea-weed as a manure, in the isles of Jersey and Guernsey, has been very extensive from time immemorial. Thus, in a work upon Jersey, by the Rev. Philip Falle, published in 1694, he observes, that "Nature having denied us the benefit of chalk, lime, and marle, has supplied us with what fully answers the end of them in husbandry— it is a sea-weed, but a weed more valuable to us than the choicest plant that grows in our gardens. We call it *vraie* (varec), in ancient records *veriscin,* and sometimes *veriscum,* and it grows on the rocks about the island. It is gathered only at certain times appointed by the magistrate and signified to the people by a public crier on a market day. There are two seasons for cutting it, the one in summer, the other about the vernal equinox. The summer *vraie,* being first well dried by the sun on the sea-shore, serves for fuel, and makes a hot, glowing fire; but the ashes are a great improvement to the soil, and are equal almost to a like quantity of lime. The winter *vraie* being spread thin on the green turf, and afterwards buried in the furrows by the plough, it is incredible how with its fat unctuous substance it ameliorates the ground, imbibing itself into it, softening the...
clod, and keeping the root of the corn moist during the most parching heats of summer. In stormy weather, the sea does often tear up from the rocks vast quantities of this weed, and casts it on the shore, where it is carefully gathered up by the glad husbandman."

The plants chiefly valued for making French varec are Fucus vesiculosus, F. nodosus, F. serratus, Laminaria digitata and bulbosa, Himationalana lorea, and Chorda filum. Twenty-four tons of the sea-weeds make one ton of kelp. The Jersey and Guernsey Agricultural Society confirmed this account of the excellent effects of the ashes from sea-weed, in 1797, in their report to the English Board of Agriculture, when they observed—

"It is judged, that a chabot (half a bushel), stroved over a perch of ground in winter or the beginning of spring, will be a sufficient manure. Our labourers are unanimously of opinion, that it gives a full ear to the corn, and prevents it being laid—those who have any varech to sell may at all times get a chabot of wheat for a quarter or six bushels of varech." (Com. to Board of Agr. vol. i. p. 216.)

The fertilizing effects of sea-weed are not confined to the better description of soils; the poorest kind of heath and lands are benefited by the application of this manure;—thus, Mr. John Sherriff, of Haddington, has described the effects of sea-weed, or sea-tang, as it is called in Scotland, on common heath or moor land, in the following terms: "Sea-weed, which is a capital manure for any land, may often be procured at little or no expense. Crops almost incredible of turnips, barley, clover, and rye, have, to the writer’s certain knowledge, been obtained on an extensive tract of the most miserable bnty wastes and poor rabbit warrens, by the powers of this manure; soils which, twelve years since, were not worth three shillings per acre. The bent was torn up by the common swing plough, burnt, and the ashes spread; the soil was then manured with the sea-tang, as much as could be ploughed in. Turnips were immediately drilled, and rolled to prevent blowing; this crop was succeeded by rye or barley, and that by red clover and rye-grass. On the clover stubble, and sometimes after the turnip crop, plenty of tang was again laid, the ley ploughed down, and sown with oats, barley, or rye, and frequently with turnips, which in this way have succeeded admirably on the ley with one ploughing." (Com. to Board of Agr. vol. iv. p. 122.) It is certain, from the experiments of the late Mr. Knight, that green manures of all kinds are an admirable manure; and it seems well established that the more the juice of the vegetables so employed is impregnated with saline matters, the more fertilizing are their effects; thus, in Bavaria, borage is very commonly cultivated for this purpose, and the reason assigned for the preference shown to this plant is, that it contains soda and other salts. (Gardener’s Mag. vol. i. p. 200.)

I have no doubt that in many situations the sea-weed may be successfully cultivated on the sea-coast, expressly for manure; and it seems that for this purpose hardly any thing is required except placing stones on the shore, to which the fungi can attach themselves, and in two years the crop may be cut. According to Mr. Jamieson (Miner. of Scottish Isles, vol. 2, p. 251), various kinds of stones have been employed in Scotland, as basalt, sandstone, and limestone, which last is the best adapted for the purpose, and after that the basalt.

There are also in many parts of the coast of Britain extensive tracts of land which it would be difficult to enclose, and yet these places are either already covered with a coarse turf, or might be so with a little management; and this turf, when cut and carted on to the light upland soils, is found almost invariably to be an admirable fertilizer—for instance, when spread over land during late winter, and then turned into the soil, for potatoes, the crop is sure to be excellent. No description of fertilizer, perhaps, can be named, which freshens, as the farmers say, an over-cropped soil so much as a dressing of from 20 to 25 loads per acre of the turf from the sea-shore, soaked with sea-water; and no plant delights in fresh soil so much as the potatoe. It is, therefore, more than probable, that the exertions of the commonly cultivated corn crops are peculiar noxious to this plant; for the potatoe, by the deposit which it leaves in the soil, renders it distasteful to the crop by which it is succeeded. Thus the wheat plant rarely looks well on soils where the potato has immediately preceded it. Saline fertilizers, in these cases, are sure to be serviceable, for they unite with, and neutralize the effects, as well as promote the decomposition, of the excretory matters which all plants deposit in the soil.

The chief fertilizing qualities possessed by barilla are attributable to the presence of soda. This alkali is found in all marine vegetables, and in most of those which grow on the sea-shore. It has been used in several experiments as a manure since the price of soda has been so much reduced; but these have not been conducted with sufficient accuracy to enable us to judge of its value as a fertilizer. What little has been done, promises well. Thus, it has been found, when a pound of soda is dissolved in 14 gallons of water, that this solution forms an excellent liquid manure for many culinary vegetables, for instance, the vegetable-marrow plant, when thus treated, has been found to flourish better in common garden mould than other plants growing on a dunghill. And, as I have remarked in another place, nature is here again our instructor: the fertile plains of Syria, and some of the most profoundly luxuriant fields of the orientalist, abound in carbonate of soda. This alkali not only enters into the composition of many vegetables, but it promotes the growth of all, by preserving the moisture of the soil, and by accelerating the decomposition of the numerous organic substances found in all cultivated lands. The sewer water of towns and cities, which has been found so very rich and fertilizing as a dressing for grass lands, abounds with soda; for that is contained in the soap suds and other refuse washings which such drainage matters always convey. Soda has been found in very sensible proportions in the urine of the horse, by M. Fourcroy; and in that of the ass, by Mr.
KELP.

Brande; and a small portion of this alkali is usually presented in the waste ashes of soap-makers, which many cultivators consider highly valuable as a manure. As the use of kelp has been of late much greater than formerly as a manure, it will be useful for the cultivator to learn the proportion of alkali contained in the kinds usually met with in commerce, as determined by Mr. Jamieson (Min. of Scottish Isls, vol. ii. p. 218):—

| Barilla from Alcant, good Teneriffe, bad | Kelp from Norway, indifferent Shetland, indifferent Lewis, indifferent West Highlands, much damaged Arran Isla, good Mull, good Morven, good Skye, good Leddshore | 23 8 | 2 11 2 6 2 6 0 5 3 8 4 8 4 8 4 8 4 0 4 0 |
